## **1.0 INTRODUCTION**

In 2005, Hurricane Katrina caused widespread damage along the Mississippi and Louisiana Gulf coasts. The Mississippi Coastal Improvement Plan was developed by the Mobile District, USACE, in conjunction with other Federal and State agencies, to help mitigate future damage along the Mississippi Gulf coast caused by hurricanes and their associated tidal surge flooding.

As part of the Comprehensive Plan, Mississippi's barrier island chain was evaluated for ways to restore it to pre-Katrina form with the overall purpose to restore its natural ability to reduce the impact of hurricanes striking the Mississippi Gulf coast. Storm events and natural sediment transport have eroded and reshaped the barrier islands into their present configuration.

This report chronicles Mobile District's geophysical and geotechnical investigations to find suitable sand borrow sources for use on the Mississippi Barrier Islands. The investigation spans more than 8 years, beginning in 2006 with initial beach sampling from the islands and concluding in 2014 with the identification and delineation of several borrow areas. Multiple agencies were involved in this investigation, including the United States Geological Survey (USGS), the National Park Service (NPS), the Bureau of Ocean Energy Management (BOEM), and the State of Mississippi. Investigative methods included geophysical surveying and geotechnical sampling.

The focus for this report is on the investigative steps taken to identify suitable sand sources for use on and around the different islands involved with the project. Each island has different sediment requirements based on engineering and biological considerations, and the report includes grain size, shape, and color information for each one. Initial placement designs were used to help establish quantities needed for each project site. However, all mentions of placement locations and borrow area shapes or dimensions are initial considerations for planning only and do not necessarily reflect their final designs. Extensive modeling has been conducted to determine optimal borrow area locations, orientations, and dimensions that will maximize sand quality and quantity while reducing potential side effects due to wave action. These final designs are included in this report, but all figures are subject to change.

Should any questions arise concerning this report or the assumed scope of work, please contact Michael FitzHarris, Geotechnical and Dam Safety Section, (251) 690-3488.

## **1.1 PROJECT DESCRIPTION**

Following Hurricane Katrina in 2005, the MsCIP was established to conduct comprehensive planning to address the following issues:

- Hurricane and storm damage reduction
- Salt water intrusion
- Shoreline erosion
- Fish and wildlife preservation
- Other water-related resource projects

One of the primary components of the Program is the Comprehensive Barrier Island Restoration Plan. Major tasks of the Plan are the following:

- Renourish the northern shoreline of West Ship Island
- Renourish the eastern shoreline of Cat Island
- Revise the dredge material disposal plan for the Pascagoula navigation channel
- Restore the sediment budget of the Mississippi barrier island chain

The Comprehensive Barrier Island Restoration Plan was developed to restore the sediment budget for the Mississippi Barrier Islands using appropriate coastal engineering designs that would maximize island chain stability while minimizing impacts to the local environment. This chain of barrier islands is located between 6 and 12 miles south of the Mississippi Gulf coastal counties of Hancock, Harrison, and Jackson Counties and consists of five natural islands and one man-made island. From west to east, the natural islands are Cat Island, West Ship Island, East Ship Island, Horn Island, and Petit Bois Island. The man-made island is Sand Island (Disposal Area 10) and it is located between Horn Island and Petit Bois Island. It was created as a disposal area for dredged material from local projects such as the Pascagoula Bar Channel. Major inlets within the island system are Ship Island Pass, Camille Cut, Dog Keys Pass, Horn Island Pass, and Petit Bois Pass. The locations of the islands, along with the location of the local navigation channels, are shown in Figure 1.1.1. In this figure, Ship Island is shown as two separate islands. It was breached during Hurricane Camille (AUG 1969) and

has remained as two separate islands since that time. Historic maps also show that Ship Island has been breached by hurricanes prior to Camille, but natural processes have closed the breaches. Except for Cat Island, all the islands are wholly owned by the NPS and are within the Gulf Islands National Seashore (GUIS). Cat Island is partly owned by the NPS, with most of the island under private ownership. The NPS' guidelines for nourishment within the park boundaries states that only sediment removed from the sediment budget due to anthropogenic activities (e.g. channel dredging) can be restored to the littoral zone. Sediment that was removed due to natural transport processes (i.e. storms, long shore currents, etc.) would not be restored. A study was conducted to determine the sediment budget loss due to anthropogenic activity within the NPS boundary and it was established at 22 million cubic yards of sand. This was based on historical dredging records for that area. This constraint means that only 22 million cubic yards of sand can be placed within the NPS-controlled area of the barrier islands. Cat Island is not completely included in this quantity. Figure 1.1.2 shows the boundaries of the Mississippi section of the GUIS.

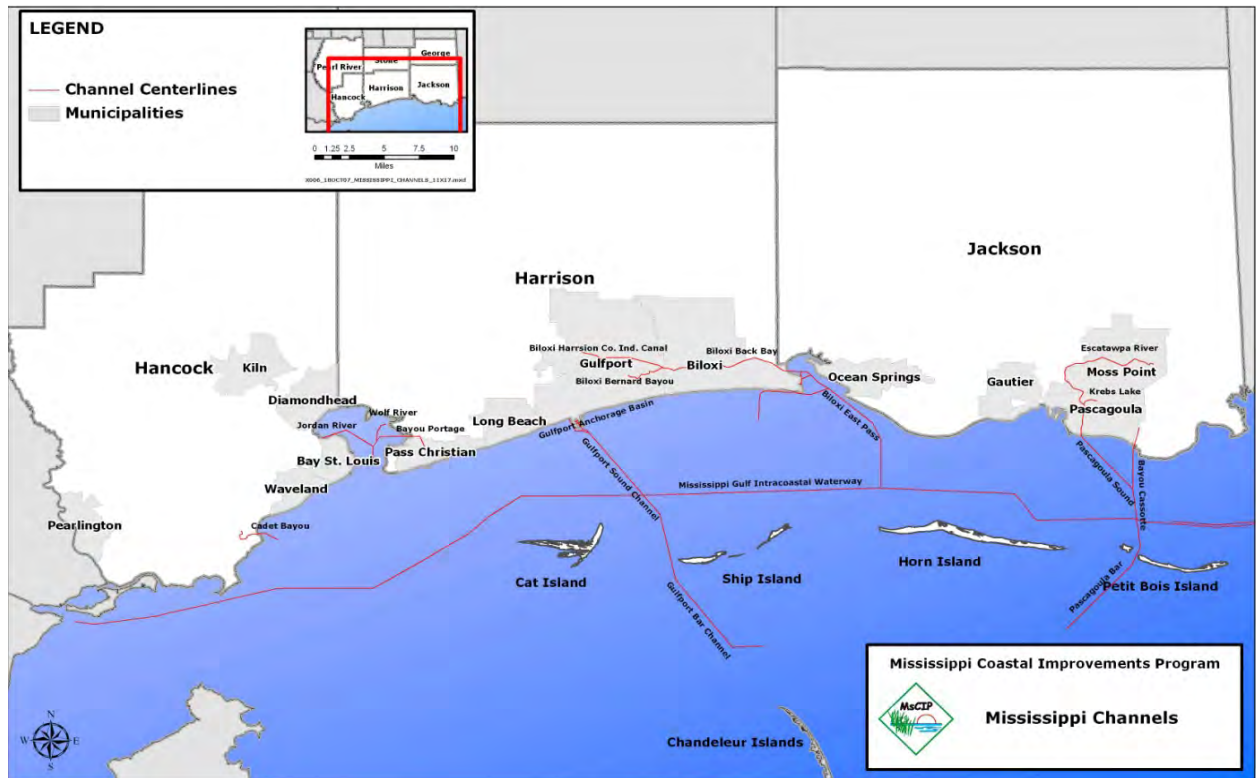

Figure 1.1.1 – The locations of the Mississippi Barrier Islands and navigation channels in the local vicinity.

**Figure 1.1.2- Boundaries of the Mississippi section of the Gulf Islands National Seashore**

The project to renourish the northern shoreline of West Ship Island was completed in the spring of 2013. A borrow area was identified for the Cat Island renourishment project as part of the 2010 and 2011 vibracore sampling events. However, that project is progressing slowly due to real estate issues. The revision of the dredge material disposal plan for the Pascagoula navigation channel has been implemented and the long term effects are being monitored. A plan has been developed to restore the sediment budget within the barrier islands system. The two major components of this plan include projects to place approximately 12.8 million cubic yards (mcy) of sand within Camille Cut to reconnect East and West Ship Islands, and direct placement of approximately 4.9 mcy of sand on the southern shoreline of East Ship Island.

## 1.2 OBJECTIVES

The objectives of this report are:

- To outline the procedures of the geotechnical investigation;
- To describe the sampling areas' grain size, fines content, color, and angularity; and,
- To identify potential borrow areas and provide estimates on borrow area sand quantities and characteristics.

## 1.3 SCOPE OF WORK

The scope of work for this geotechnical engineering study was derived from the project requirements and includes the following technical approaches:

- Identify areas of potential sand resources based on past studies and utilizing subject matter experts from the USGS, the BOEM, and other governmental and non-governmental organizations.

- Conduct geophysical surveys to identify potential sand deposits.
- Conduct vibracore sampling of the deposits and sample potentially useable sediments for further lab testing.
- Conduct laboratory testing of samples for grain size, angularity, percent fine material, calcium carbonate content, and color.
- Use the spatial and textural data to identify areas with suitable borrow material in economical quantities.

### 1.3.1 BEACH AND ISLAND SEDIMENT SAMPLING

Beginning in 2006, grab-sampling events were conducted by USACE personnel along the Mississippi Barrier Islands (Figure 1.3.1.1). The intent of the sampling was to identify typical sediment characteristics within the barrier island system.

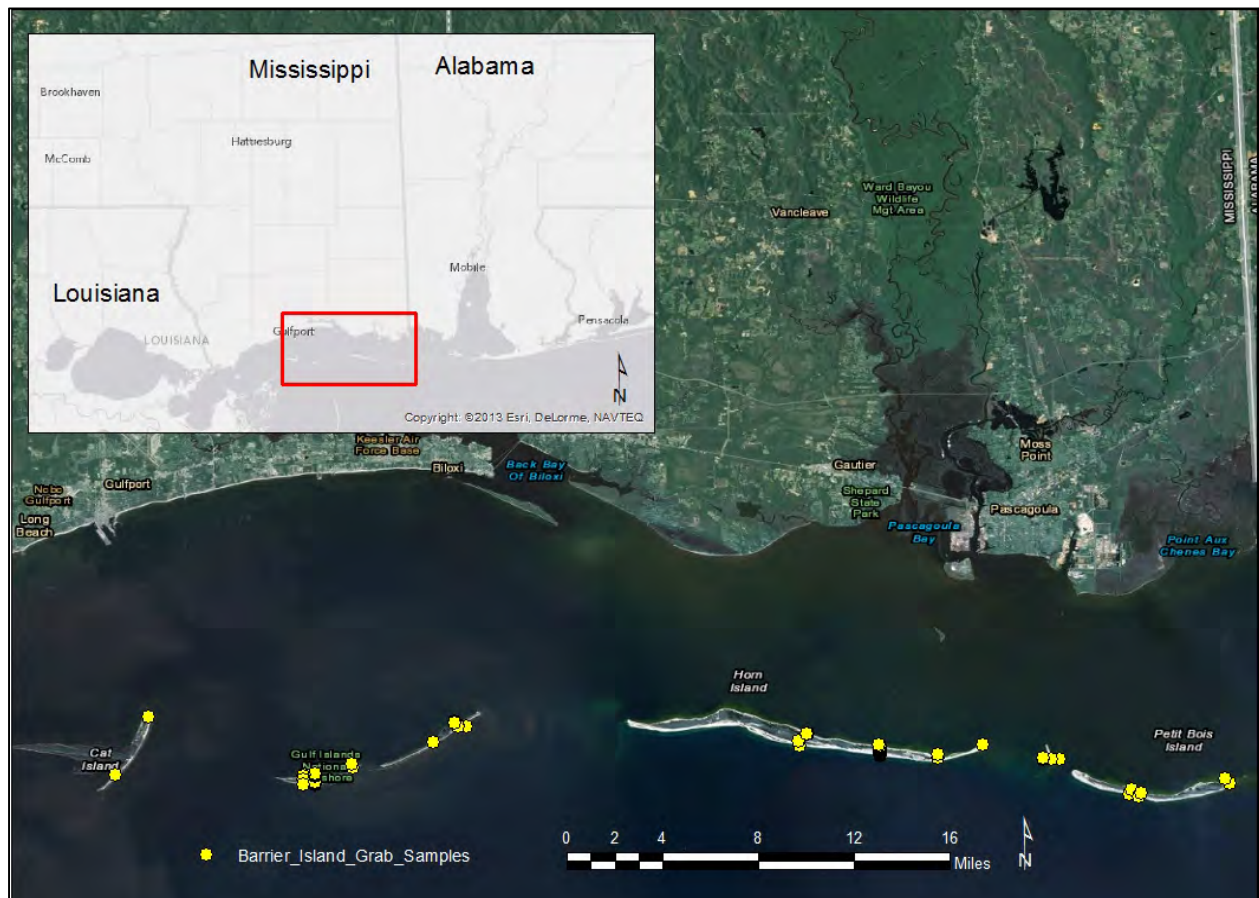

Figure 1.3.1.1- Sediment grab sample locations within the Mississippi section of the Gulf Islands National Seashore and Cat Island.

Based on the sampling, the following sediment characteristics and in situ condition baselines were established for potential sand sources for the Camille Cut and East Ship Island projects.

**Table 1.3.1.1 Baselines for suitable sediment characteristics and borrow areas**

Characteristic	Baseline
Sand layer thickness	Greater than or equal to 4 ft.
D50 Grain Size range	0.26 to 0.32 mm
Percent Fines	Less than 15% silt and/or clay content
Color	Dry Munsell Color Value greater than or equal to 6
Overburden / unsuitable sediments	≤ 2 feet of unsuitable material on top of the sand, or, throughout the entire useable thickness of sand with at least 4 feet of suitable material intermixed
Location	Outside active littoral zone; Outside GUIS boundaries; Within economical distance to placement sites

Although borrow area location was initially restricted to areas outside of the GUIS boundaries during the 2010 geotechnical investigation, the findings of the Engineer Research and Development Center / Coastal and Hydraulics Laboratory Technical Report-12-9 “Littoral Sediment Budget for the Mississippi Sound Barrier Islands” (Byrnes et al., 2012) identified DA-10 (Sand Island) as a potential sand source because of its position within Horn Island Pass and the effect this had on the barrier island littoral system. This report provided a justification for sampling the area adjacent to DA-10 during the 2011 geotechnical sampling event. For the purposes of the 2012 and 2013 sampling events, no areas were sampled within the GUIS boundaries or within the littoral zone. Section 3 details these island sediment sampling events.

### 1.3.2 GEOPHYSICAL SURVEYS

The USGS, in conjunction with USACE, the NPS, and the State of Mississippi, conducted three major geophysical surveys in the areas surrounding the barrier islands. The first survey was in 2009, the second survey in 2010, and the third survey in 2013. The two main purposes of these surveys were to gather information about the geological setting surrounding the islands and further offshore from Petit Bois Island, and to identify possible sources of sandy material for use with the barrier island restoration project. Section 4.0 details these surveys.

**1.3.3 GEOTECHNICAL INVESTIGATION**

For the geotechnical investigation, vibracore sampling was used to collect sediment samples in areas identified by the USGS as having potentially suitable sand. These samples were then laboratory-tested and classified according to the Unified Soils Classification System (USCS). Sampling was conducted from 2010-2014. The 2010 vibracore sampling locations were initially identified during the preceding geophysical surveys (see Section 4.0) and were altered and augmented throughout the sampling event based on the real-time results of the sampling. It consisted of 369 vibracores scattered across the barrier island chain's waters, from Gulfport Channel in the west to Petit Bois Pass in the east. The 2011 sampling event only consisted of 89 vibracores near Cat Island, DA-10, and the Petit Bois Pass area. The 2012 sampling event consisted of 230 vibracores and focused on Horn Island Pass, Petit Bois Pass (Alabama and Mississippi waters), and the Outer Continental Shelf area south of Petit Bois Island. Following the USGS's geophysical survey in August 2013, the 2013 sampling event consisted of 206 vibracores and focused on Horn Island Pass and the OCS area south of Petit Bois Island. Figure 1.3.3.1 outlines the sampling areas and Table 1.3.3.1 shows the breakdown of vibracores and lab samples per sampling event. Vibracores containing visually suitable material for use in the project placement areas were sampled. All other material was discarded. The samples were lab-tested to determine grain size distribution and percentage of fine material, while qualitative Munsell color classification and grain angularity classification were conducted mostly by USACE personnel. These test results helped determine if a particular vibracore's contents met the fill textural characteristics criteria established during the beach and island sediment sampling events. The vibracores containing suitable sediments were then spatially analyzed to delineate potential borrow areas. Section 5.0 details this investigation.

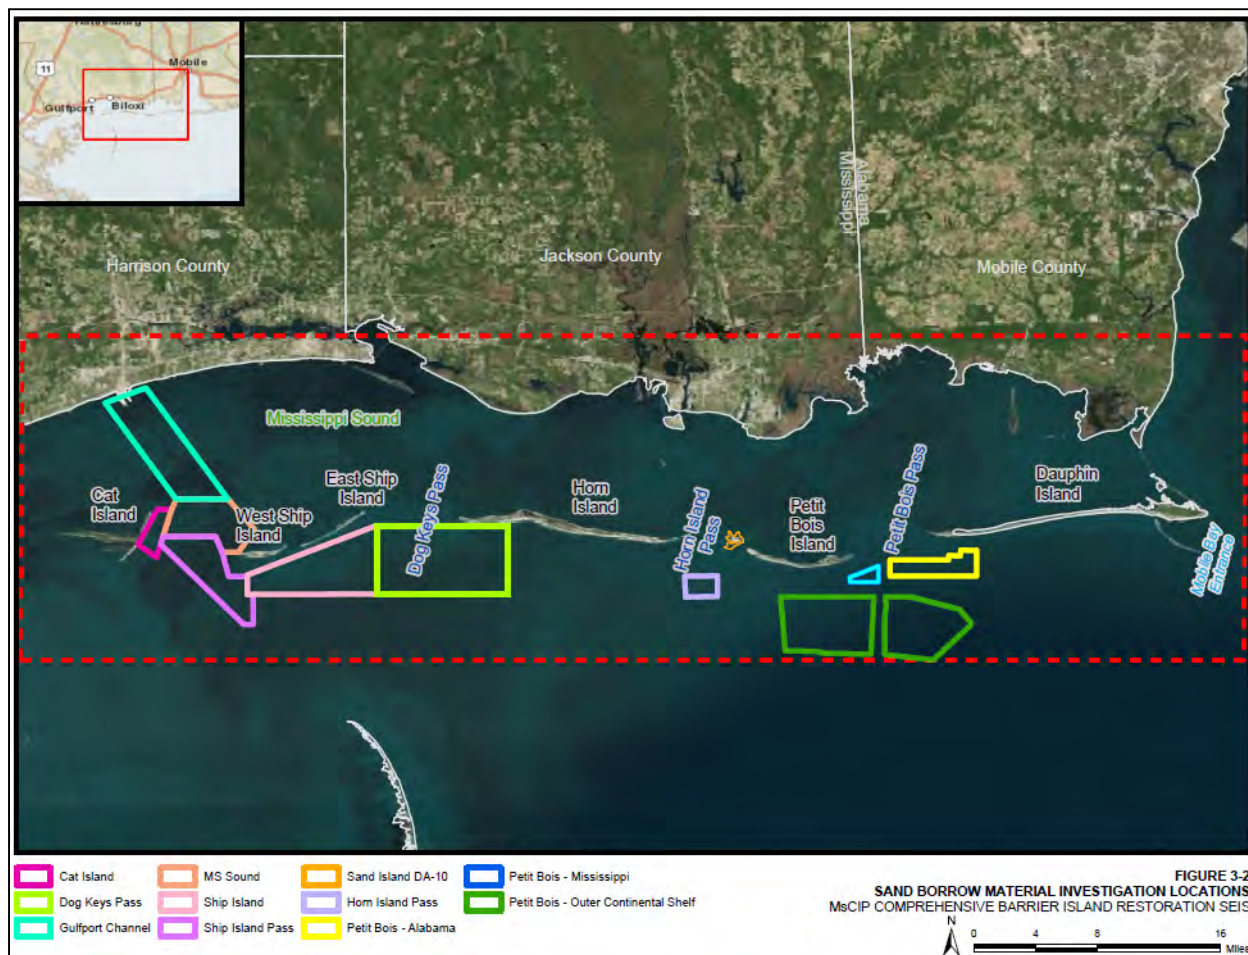

Figure 1.3.3.1- Borrow Material Investigation Locations (Figure 3-2 from USACE SEIS, 2014)

Table 1.3.3.1 Number of vibracores and lab samples per sampling event.

Sampling Event	No. of Vibracores	No. of Lab Samples
2010	369	649
2011	89	176
2012	230	488
2013	206	455
Total	894	1,768

### 1.3.4 INVESTIGATION RESULTS

From 2010-2014, each sampling event either identified or refined potential borrow areas. Potential borrow areas were identified just east of Cat Island, just west of West Ship Island, south of West Ship Island, south of Horn Island Pass, south of Petit Bois Island in Mississippi state waters, south of Petit Bois Island in Federal waters, and south of Petit Bois Pass in Alabama state waters. Figure 1.3.4.1 highlights these areas.

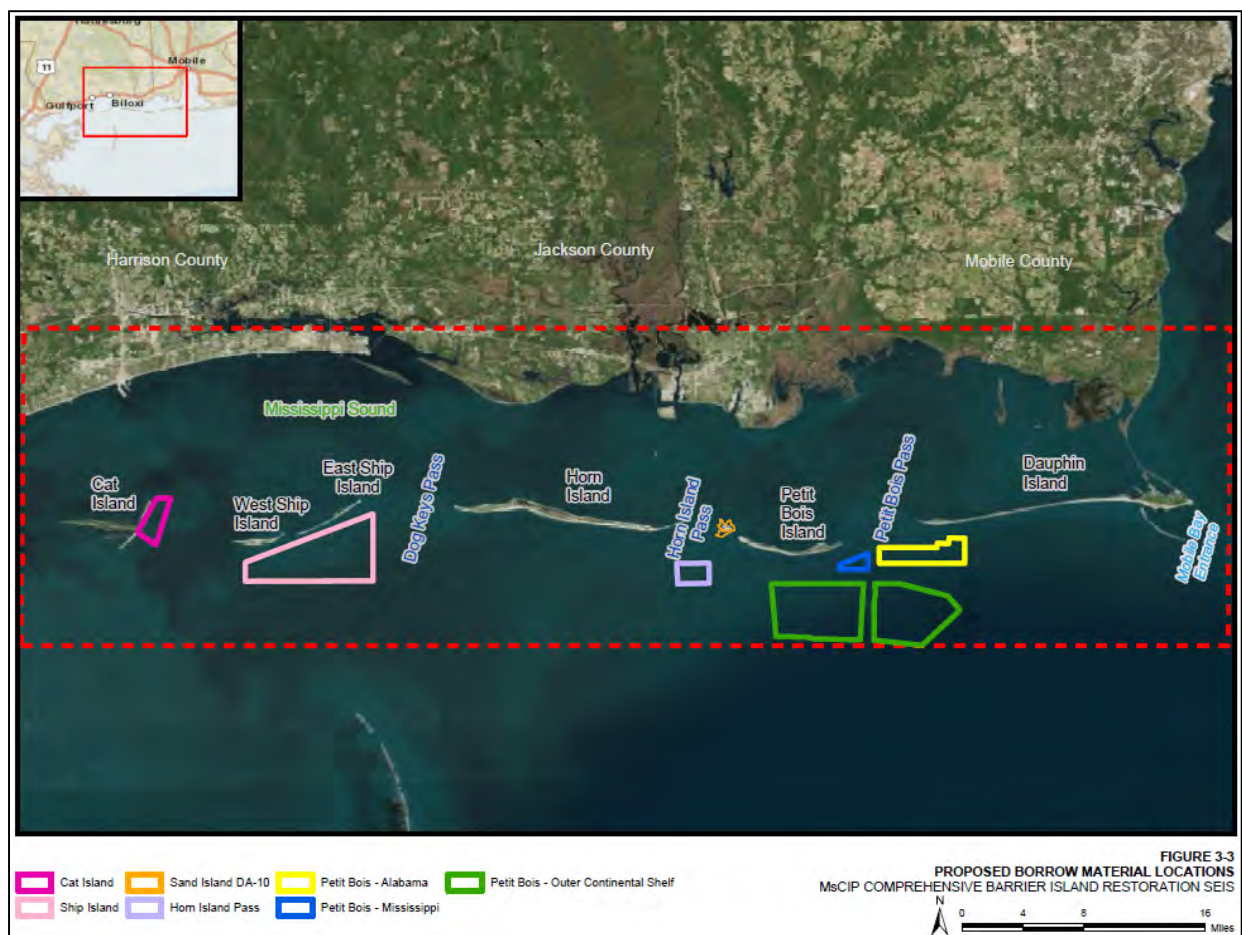

Figure 1.3.4.1- Proposed borrow material locations (Figure 3-3 from USACE SEIS, 2014)

The following table is a consolidated list of the spatial and textural characteristics for each of the new potential borrow areas.

**Table 1.3.4.1 Potential Borrow Area Characteristics**

<i><b>Borrow Area</b></i>	<i><b>Template Volume (mcy)<sup>2</sup></b></i>	<i><b>Area (Acres)<sup>3</sup></b></i>	<i><b>D50 (mm)</b></i>	<i><b>Percent Fines</b></i>	<i><b>Dry Munsell Value</b></i>
Petit Bois Pass-Alabama East	14.7	885	0.33	7	6
Petit Bois Pass-Alabama West	5.1	380	0.31	4	6
Petit Bois Pass-Mississippi	2.0	175	0.31	3	7
Petit Bois Pass-Outer Continental Shelf East	4.2	464	0.29	2	7
Petit Bois Pass-Outer Continental Shelf West	15.4	1,383	0.27	3.4	6
Horn Island Pass	4.9	612	0.28	4.4	7
Ship Island	2.7	183	0.21	6	7
Ship Island Pass <sup>1</sup>	0.45	20.9	0.48	< 1	6
Cat Island	4.3	429	0.20	5	6
Total	53.7				

<sup>1</sup>The Ship Island Pass borrow area was used for the West Ship Island North Shore Restoration Project.

<sup>2</sup>Borrow area template volume does not include estimated losses caused by dredging inefficiencies. Template volume includes the estimated required dredge volume and the estimated allowable dredge volume.

<sup>3</sup>Borrow area acreages are estimated based on cut bottom area and do not include side slopes.

These values are estimates. While borrow area designs attempt to optimize the in situ characteristics of the sediments within their boundaries, sediment characteristics in the fill template will vary due to natural variability in the borrow area, dredging efficiency, handling and placement losses, placement method, and, ultimately, natural processes (wind, waves, and precipitation) at the placement site winnowing out finer sediments as the fill settles into equilibrium with site conditions.

## **2.0 GEOLOGICAL SETTING**

The study area for this geotechnical report is a subset of the MsCIP study area and includes the barrier islands and surrounding waters off the Mississippi coast and south of Alabama's western end of Dauphin Island. The study area also includes an area of the outer continental shelf located approximately south and southeast of Petit Bois Island, MS. The purpose of this section is to provide an overview of the geology for the study area in order to better understand where potential sand sources might be located.

### **2.1 GULF COASTAL PLAIN**

The coastal area of Mississippi is part of the Gulf Coastal Plain which extends from Florida westward to Texas. This plain includes the barrier island chain which lies 6 to 12 miles offshore and that is of interest for this project. This island chain consists of the following islands: (east to west) Petit Bois, Horn, East Ship, West Ship, and Cat Islands. It was first thought of this area to be remnants of topographic highs of the upland surface that had been separated from the mainland by marine inundation as the Gulf Coast slowly subsided (McGee, 1891). However, this interpretation was proven to be incorrect after accurately dating and correlating the stratigraphy and sediments of the Coastal Plains through core sampling (Morton, 1977).

Interpretations of these cores led to indicate the gradual near shore sediment aggradation that led to the formation of the narrow, sandy platform belt over the lower muddy-sandy nearshore deposits (Otvoš, 1985). This near surface deposit stratigraphy of the Mississippi-Alabama Shelf is the product of the fluvial-deltaic deposition during sea level lowstands that have occurred since the late Pleistocene. The gulfward growth of the deltas during the glacio-eustatic fluctuations in sea level produced stacked, off-lapped sedimentary sequences derived from the Mississippi, Pearl, Pascagoula, Tombigbee, Alabama, and west Florida river watersheds. During the late Pleistocene, deltaic loads from the fluvial systems produced differential rates of subsidence of the shelf which acts as the primary mechanism for fluvial orientation and shelf geometry (Bartek et al, 2004). During this time period, sea level changes associated with global glacial action caused a transgressive-regressive sequence reworking sand along the coast. The last glacial period created a coastline near the edge of the continental shelf. As the ice began to melt, the associated sea level rise and wave action began to form the exposed sand into barrier islands with replenishment to this system coming from the east associated

with sediments from the Apalachicola River that contribute to the barrier islands in northwest Florida westward into Alabama along Dauphin Island.

The sediment supply of the barrier islands is transported by the long shore littoral drift moving from the east to the west, along with Mobile Bay's huge ebb-tidal delta which receives sand intermixed with dominant mud from the Bay interior by powerful tidal currents. A relic late Pleistocene barrier ridge on the western flank of the Bay entrance became the intermediate base that enabled continued westward sand transport by littoral drift and currents off, and parallel with, the mainland shore which sourced sediment for the northern Gulf of Mexico barrier islands (Otvos, 1981). The relics of the earliest islands are buried under deltaic deposits and preserved west of the Square Handkerchief Shoals, approximately 2-3 miles south of Bay St. Louis, MS. The littoral drift reaches Petit Bois Island and the other islands via the shoals and ebb-tide deltas south of the inter-island passes (Otvos, 1985). However, growth of the St. Bernard sub-deltas of the Mississippi River south of Hancock and Harrison Counties in Mississippi resulted in the cutoff of the littoral drift west of Ship Island approximately 4,000 years ago (Frazer, 1967).

## **2.2 JACKSON, HARRISON, AND HANCOCK COUNTIES**

The Geologic Map of Mississippi (Moore, 1976), published by the Mississippi Geological Survey, identifies three strata, or formations, that underlie the three subject counties north of the barrier islands. These include the alluvial/coastal deposits of Holocene age, the Citronelle formation of Pliocene/Pleistocene age, and the Pascagoula/Hattiesburg formation of Miocene age. Otvos (1986, 1992, and 2005) further defines the various formations and provides information to their depositional environment. These formations and environments also apply to the barrier islands concerning this project. The later work addresses the presence of, or lack of, sand and other sediments along the coast, in the Mississippi Sound and near the barrier islands.

Within the Mississippi Sound, Holocene-aged deposits form thin, muddy strata that cover the older Pleistocene formations. These include alluvial, estuarine, and lagoonal-bay deposits. Sampling studies have shown the strata to contain particle sizes from colloidal to sand size depending on the energy associated with its depositional environment (Upshaw, Creath and Brooks, 1966).

The transgressive-regressive sequence, which reworked the sand and other sediments along the coast, resulted in three formations that correlate from the alluvium along the coast to the barrier islands: the Prairie, Biloxi, and Gulfport formations. The Gulfport and Prairie formations are generally very sandy and have some economic value because of this characteristic. A generalized geologic map of the Mississippi coast based on these studies is shown in Figure 2.1, (after Otvos, 1997). The Prairie formation is found just landward of the coast in all three counties, while the Gulfport formation is found along the beaches and barrier islands.

Figure 2.2.1 - Generalized Geologic Map of Coastal Mississippi (After Otvos, 1997)

## 2.3 OUTER CONTINENTAL SHELF

The following is an excerpt from the 2014 USGS report, *Near-surface stratigraphy and morphology, Mississippi inner shelf, northern Gulf of Mexico*, describing the modern morphological setting for this region.

The area south of the barrier islands is “the inner Mississippi-Alabama shelf, which is a slowly subsiding, passive continental margin bound to the west by the Mississippi River delta and to the east by the DeSoto Canyon located offshore of the Florida panhandle (Sydow and Roberts, 1994). The shallow stratigraphy of this region is the product of fluvial-marine sedimentation, driven by sea-level oscillations during the late Pleistocene and into the Holocene (Flocks and others, 2011b). During periods of lower sea level, the region was a flat, low elevation coastal plain, with low gradient rivers meandering across older shelf stratigraphy (Kindinger and others, 1994; Bartek and others, 2004). Within the study area, fluvial systems that extended across the shelf are related to the modern watersheds of southern Mississippi and Alabama (e.g. Fowl, Bayou La Batre, Pascagoula, and Pearl Rivers). Throughout the Holocene, sea-level rise flooded the coastal plain, infilling the river embayments with sediment and forcing bayhead deltas to migrate upstream (Bart and Anderson, 2004). Burial of these transgressive deposits produced the most complete stratigraphic component of inner-shelf features. Tidal inlet and barrier island development seaward of the embayments were inundated by rapid sea-level rise and reworked into expansive sand sheets and shoals comprised of moderately sorted, medium to fine sand (Doyle and Sparks, 1980). West of present day Mobile Bay, shoals are rare and occur almost exclusive to the area between Dauphin and Petit Bois Islands. These shoals are stable features extending from ~4 to 20 m water depth (13.1 to 65.6 feet). They trend NW-SE, parallel to the prevailing wave climate, and are composed of poor to moderately-sorted, medium sand (Flocks and others, 2011a). By about 5 thousand years before present (kyr BP), sea-level rise reached the position of GUIs, and a dominant westward littoral system initiated the development of the barrier islands. Sediment supply for the islands was sourced primarily from the Mobile River embayment deposits (Otvos, 1981; Greene and others, 2007). As sea level reached its present position, the St. Bernard delta complex of the Mississippi River delta encroached into the western Mississippi-Alabama shelf, covering the backfilled stratigraphy with muddy, prodelta deposits until delta development ceased about 2 kyr BP (Otvos and Giardino, 2005), completing the modern morphologic setting of the inner shelf.” (Flocks, 2014)

Section 4 includes more details about the geology and geomorphology of the sampling areas, with emphasis on potential borrow sites, while discussing the

USGS's 2010 and 2013 geophysical surveys around the GUIS islands and south of Petit Bois Island.

### **3.0 PLACEMENT SITE FIELD INVESTIGATIONS**

Textural and color characteristics of the native material at the placement sites are critical to determining the fill characteristics required to meet the project's objectives. Before any borrow area investigation could begin in earnest, sediments at the placement sites had to be analyzed to determine their textural and color characteristics.

#### **3.1 FILL COMPATIBILITY REQUIREMENTS**

Shorelines are dynamic environments and vary spatially and temporally. Therefore, determining the in situ characteristics of the placement areas is challenging. Fill material should match native material as closely as possible to ensure stability and minimize environmental impacts due to changes in material characteristics. Color, grain size, shape, and carbonate content all affect the engineering and environmental characteristics of the fill. General guidelines for identification of compatible borrow were reviewed in USACE publications, as well as other agency publications such as the National Oceanic and Atmospheric Administration's (NOAA) publication, "Beach Nourishment: A Guideline for Local Government Officials" and Florida's Department of Environmental Protection guide for selecting borrow material for beach nourishment projects.

##### **3.1.1 COLOR**

The color of beach sand is an issue not only for aesthetics, but it also affects marine life. The color of the sand directly affects the absorption of solar energy from the sun, which in turn affects the temperature of the sand. Darker sand absorbs more solar energy, making it warmer than lighter colored sand which reflects more of the solar energy. Temperature plays a role in determining the gender of sea turtle hatchlings. Researchers have discovered that the warmer the sand, the higher the percentage of female sea turtle hatchlings that develop (Hayes, G.C.; et al.). For this investigation, samples were qualitatively analyzed and assigned a Munsell Color Munsell color hue, value, and chroma classification (ASTM D1535-12a) in order to quantitatively compare each sample. For the purposes of classifying the color of large borrow areas, the Munsell value is used because it describes the material's lightness on a continuous scale from 1 to 10. 1 is black and 10 is white, with shades of gray in between. The value gives an indication to the lightness of the sediment, regardless of its hue or chroma, thus simplifying comparisons between samples that

might have different hues. In general, a wet sample is one to two Munsell values darker than a dried sample. Because moisture affects color, wet and dry color characterization was done for each sample. For this report, a volumetrically-weighted average Munsell value was used for describing the sediment for borrow areas and placement areas when possible.

### **3.1.2 GRAIN SIZE**

The grain size distribution, or gradation, of a sediment sample refers to the range of particle sizes contained in the sample and is a significant factor for nourishment projects because particle size distribution directly affects beach fill stability and the equilibrium profile's slope. Existing beach sediments are typically in a state of equilibrium with the energy from waves and currents surrounding them. Generally, the sediments finer (smaller) than those in equilibrium with these surrounding conditions will be transported away by wind, waves, and currents, leaving only the proper particle size based on existing environmental conditions (Dean, 1974 and 1991). Coarser (larger) grain sizes require relatively greater energy to be moved, in comparison to finer grains, so coarser sands generally remain in place (unless a significant storm event occurs), thereby increasing beach stability. Coarser grained sand also has a steeper angle of repose, which produces steeper equilibrium profiles.

Although no single statistic can completely describe a sediment's grain size distribution, the D50 (median grain size, in mm) was used because it provided a more conservative estimate of the approximate average sample grain size due to the poorly graded (relatively uniform) nature of the samples. Therefore, when possible, volumetrically-weighted average D50 was used for describing the sediment size for borrow areas and placement areas.

### **3.1.3 GRAIN ANGULARITY**

The angularity, or roundness, of individual grains affects sediment settling, compaction, and motion initiation. The sand found on the barrier islands is typically a sub-angular to rounded shape, which is expected with sand grains that have been transported over long distances. More angular sand grains tend to pack tightly together and make a harder beach surface, while rounded sand grains tend to be less compacted and contain a higher porosity. These variations in the firmness of

the surface will affect the use of the islands by many types of fauna. Nesting sea turtles prefer sand that is loosely packed for nesting. The more rounded sand grains allow for easier nest digging by the turtles. Changes in the compaction of the beaches will also affect the benthic community at the shoreline, which will in turn influence the use of the beaches by shorebirds. USACE and NPS personnel qualitatively compared a representative sample from each vibracore sample to a Geotechnical Gauge containing different degrees of angularity to determine the overall angularity of that sample. Compaction testing on the native beaches was not conducted.

### **3.1.4 CARBONATE CONTENT**

Beach sands can be broadly categorized by their chemical composition into either carbonate ( $\text{CaCO}_3$ ) beaches or siliciclastic/quartz ( $\text{SiO}_2$ ) beaches. Carbonate content is important because carbonate sands perform differently from silica sands due to different intraparticle porosities, density, bulk density, and structural integrity of carbonate grains (Halley, 2000). Weathering of carbonates can produce sediments with higher concentrations of silt- and clay-sized material resulting in cementation of grains and elevated turbidity. Carbonate content was generally not an issue with this investigation because the vast majority of sand located was siliciclastic / quartz with very little shell fragments. That is not to say that there will not be shell fragments in the borrow material, but the overwhelming constituent of the borrow material will be quartz sand. Quartz sand is very resistant to physical and chemical weathering, so sand of this type will tend to have less turbidity and cementation issues in the long term.

### **3.1.5 FINE SEDIMENT CONTENT**

The Unified Soil Classification System (USCS) defines fine sediment, or fines, as any sediment that passes through a U.S. Standard #200 (0.074 mm) sieve. This fine sediment can be either silt- or clay-size particles. Fines affect the overall quality of the sand. It increases turbidity in the foreshore area and, in significant amounts, can alter the engineering properties of the sand. Aesthetically, quartz sand with a high percentage of fine material tends to look dirty and is not appealing to beachgoers. Therefore, clean quartz sand with less than 5% fine sediment is optimal and 10% or less fines is acceptable. The NPS was willing to allow up to 10% fine material on beaches (15% in the nearshore area) because of natural

sorting that occurs along the coast over time. The dredging and placement process will winnow out fine sediments as well. When hopper dredges are filling up, the fine sediments will tend to stay in suspension and be pushed out of the hold with the water as it is filled up. Further, silty or clayey sand are expected to contain less fine sediments after placement because the fines are again in suspension during placement and will likely be dispersed during hydraulic placement and through subsequent natural coastal processes. Because of the anticipated loss of fines due to dredging and natural coastal processes, sand sources with fines up to 15% were considered acceptable.

### 3.2 BARRIER ISLAND SEDIMENT SAMPLING

Multiple beach and island sediment sampling events took place between 2006 and 2011 (Figure 3.2.1). Their purpose was to identify the native materials' textural characteristics in order to determine the best matching fill for the projects. Samples were taken from sandy sediments that were most representative; relatively small exposed deposits of clay or peat were not sampled and tested.

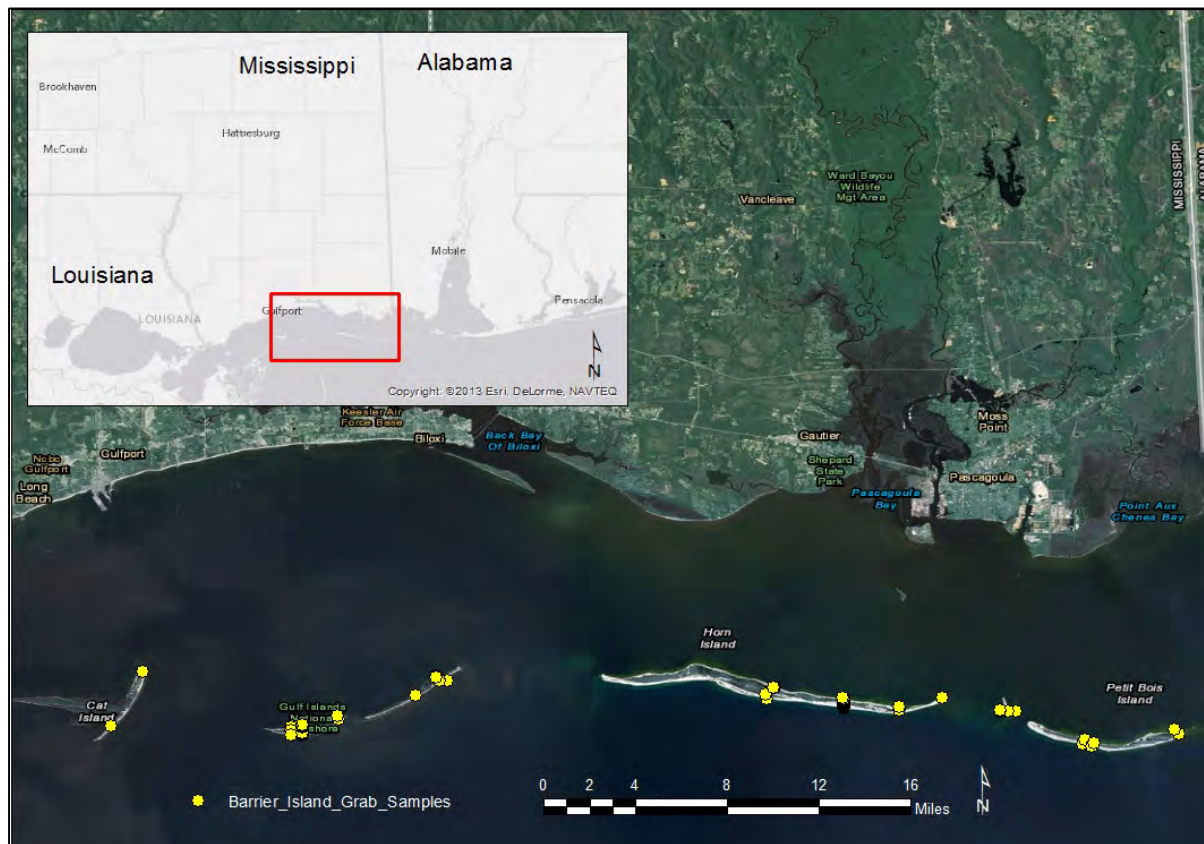

Figure 3.2.1 Barrier Island grab sample locations

**3.2.1 2006 BEACH SEDIMENT INVESTIGATIONS**

During initial stages of the Barrier Island Plan in 2006, geologists and biologists from the USACE Mobile District took samples from various locations on beaches on Petit Bois, Horn, East Ship, and West Ship Islands. Cat Island was not included in the project plan at this time. These samples were analyzed for color using Munsell Color Charts and for angularity by qualitative comparison using a McCollough Geotechnical Gauge. The samples were not lab-tested for grain size distribution, but were visually-manually classified according to the USCS. The results of the sampling indicated that the majority of the sediments were poorly graded, sand-sized quartz, light gray in color, with sub-angular to rounded particle shape. The results of the sampling are shown in Table 3.2.1.1. Aerial imagery maps for the 2006 sampling events are shown in Appendix A.

**3.2.2 2009 BEACH SEDIMENT INVESTIGATIONS**

In 2009, a sampling event was completed on all the GUIS islands, including Cat Island. This event was performed by personnel from the USACE Mobile District, accompanied by a coastal geomorphologist from the NPS Regional Office in Atlanta, GA. In addition to qualitatively determining the Munsell color and particle shape, the samples were taken to a soils laboratory for grain size analysis. The samples were analyzed using methods contained in ASTM D2487, "Practice for Classification of Soils for Engineering Purposes (Unified Soil Classification System)". Selected results of the grain size analyses are shown in Table 3.2.2.1 and complete results are shown in Appendix A. The sampling locations and the results of the qualitative color and particle shape classification are shown in Table 3.2.2.2.

Note: Colors in Table 3.2.2.2 may differ from the colors listed on the lab reports in Appendix A because the lab did not conduct a color analysis using a Munsell Soil Color Chart and USACE personnel did the classification after receiving the lab results.

**3.2.3 2010 BEACH SEDIMENT INVESTIGATIONS**

Beaches are relatively high energy environments compared to the interior portions of the islands and the variation of sediment grain size across the islands was not known. Two transects were established; one on West Ship Island and another on Horn Island. Each transect had 11 sample locations spaced across the island from the Sound to the Gulf. Each location was sampled from the surface to a depth of approximately one foot. Each sample was sent to an engineering laboratory for a grain size analysis. In addition, an equal amount of sediment from each sample, from each of the islands, was composited into an additional sample for a separate analysis. The intent of the composite samples was to characterize the entire island along that transect. The location of the samples taken at West Ship Island and Horn Island are plotted on imagery in Figures 3.2.3.1 and 3.2.3.2, respectively. Native material for both islands proved to be mostly poorly graded, medium-grained, sand-sized quartz with trace fine sediments. Grain size undulates along the transect, going from finer grain in deeper water, coarsening with decreasing water depth, and then becoming finer towards the center of the island in the subaerial samples.

For West Ship Island, the sampling results show that the locations in deeper water (WSI-1-10 and WSI-11-10) had smaller grain sizes than those samples in the shallower, more active areas of the foreshore (WSI-3-10, WSI-10-10, and WSI-9-10). The smallest grain sizes were in samples located towards the center of the island (WSI-5-10 and WSI-6-10). The samples on the northern side of the island were generally larger in size as well. This may be due to the decreased wave energy on the Sound-side of the island and subsequent reduction in transport capacity of the coarser grain sizes, thus leaving the coarser sediment in place. Whereas, the south shore is subject to greater wave energy which is capable of transporting coarser material. Previous storm overwash may have also had the energy to transport and deposit the coarser grain sizes from the gulf-side of the island to the sound-side. However, these samples are from discrete locations and the depositional environment when they were deposited, along with the subsequent reworking due to coastal processes, affects the gradational consistency throughout the island. Therefore, other locations could show slightly different gradation results. Despite this variability, the majority of the island is expected to be poorly graded, medium to fine grain, sand-sized quartz with minimal (<5%) fine sediment content. Selected results of the grain size analyses are shown in Tables 3.2.3.1 and 3.2.3.2, with complete results included in Appendix A.

Figure 3.2.3.1 – Location of sampling locations for 2010 West Ship Island beach transect.

For Horn Island, the sampling results indicated a similar pattern as the West Ship Island samples. Finer grain sizes in the deeper water (HI-1-10, HI-11-10) and coarsening shoreward as the water depth decreases. The middle of the island is slightly finer than the beaches on either side. As with West Ship Island, grain size will vary throughout the island due to natural processes, but the majority of the island is expected to consist mostly of poorly graded, medium-grained, sand-sized quartz with minimal (<5%) fine sediment content.

**Figure 3.2.3.3 – Bar graph comparison of grain sizes for West Ship and Horn Island beach transects.**

Figure 3.2.3.3 graphs the sampling results, minus the composite samples, and illustrates the undulating grain sizes based on the sample location on the transect. It must also be taken into account that the samples along each transect were not necessarily in the exact same relative location on the island as the counterpart sample (i.e. WSI-5 and HI-5 are not exactly in the center of their respective island). The graph does not model accurately these variations. Although the sample locations are not exactly the same, the general pattern of fluctuation across the transect is similar across both islands, corresponding to roughly the same geologic features of their respective island. Also of note, the West Ship Island samples were generally finer than the Horn Island samples which is indicative of it being further down drift from the sediment source feeding the island chain.

Further discussions within the Engineering team led to another round of sampling on West Ship Island (Figure 3.2.3.4). These samples were taken as composites, with total depths ranging from 4.0 to 5.0 feet below ground surface. The purpose of these samples was to determine if there were any significant differences in sediment characteristics because of the sample's stratigraphic position. The samples' coordinates and selected results of the gradation analysis are shown in Table 3.2.3.3.

The results do not indicate a significant change in material type (poorly graded quartz sand) from the surface to the target depth of 4.0 – 5.0 ft below ground surface. Results did indicate that grain size was slightly larger on the southern side of the island. However, the results are so close (range of 0.05 mm) that they do not indicate a significant variation to the overall characteristics of the island's surficial sediments.

Figure 3.2.3.4 shows the layout of the 2010 samples on West Ship Island and gradation curves are included in Appendix A.

Both sampling events demonstrate that the majority of sediment on the barrier islands is poorly graded, medium to fine grained sand-sized quartz with minimal (<5%) fine sediments. However, the aerial photos illustrate that other finer grained material (clays and/or silts) can be found surficially on both islands as evidenced by the darker colors, ponded water, and more robust vegetation. These deposits are encountered mostly on the interior of the islands where wave action cannot winnow out the fines and transport them away.

### 3.2.4 2011 DA-10/SAND ISLAND SAMPLING

Three grab samples were taken from the DA-10 / Sand Island in 2011 to further characterize the sediment on the island. Because it is dredged sediment from the Pascagoula Shipping Channel, the island contained very clean, poorly graded, medium-grained, sand-sized quartz with less than 2% fine material. As with Horn and West Ship Island, the interior sample (BI-DA10-16-11) did contain slightly finer sand than the two samples closer to the water line. Table 3.2.4.1 shows the lab results for the samples. Figure 3.2.4.1 shows the layout of the samples on the island. Lab reports are included in Appendix A.

### 3.2.5 BARRIER ISLAND SEDIMENT SAMPLING CONCLUSION

The island sampling events from 2006 to 2011 helped to evaluate the different sediment gradations throughout the barrier islands and characterize the different placement sites for the upcoming projects. As expected, grain size distribution is spatially variable on each island and directly affected by the geographic location of the sample. Specifically, coarser grain sizes were typically found in areas of higher energy along the beaches, while samples located in deeper waters and towards the

interiors of the islands were finer-grained. Grain sizes also typically became finer from east to west along the island chain. Table 3.2.5.1 is a summarized listing of the surficial sediments for Cat Island, West and East Ship Islands, Horn Island, DA-10, and Petit Bois Island. D<sub>50</sub> values for Cat Island, Petit Bois Island, and DA-10 were calculated using an arithmetic mean of the D<sub>50</sub>s of the grab samples taken on the islands (Table 3.2.2.1 and Table 3.2.4.1). Horn Island's and West Ship Island's composite sample D<sub>50</sub>s were used to represent the average D<sub>50</sub> on these islands. The Camille Cut placement site was not sampled directly to determine grain size. Rather, grain size information from the western tip of East Ship Island (ES-1-09) and the eastern tip of West Ship Island (WSI-4-09) were used as proxies. As such, Camille Cut fill should have a D<sub>50</sub> grain size of approximately 0.28 mm, ranging to as coarse as 0.34 mm, to most closely match the native material on the tips of East and West Ship Islands.

**Table 3.2.5.1 – Surficial sediment information for barrier islands**

## 4.0 GEOPHYSICAL INVESTIGATIONS

The USGS conducted geophysical surveys in 2009, 2010, and 2013 to identify offshore areas with sandy material. This section details these investigations.

### 4.1 2010 GEOPHYSICAL SURVEY

Since 2007, the USGS has conducted geophysical surveys in collaboration with the NPS within GUIS park boundaries as part of the USGS Northern Gulf of Mexico (NGOM) Ecosystem Change and Hazard Susceptibility project (Figure 4.1.1).

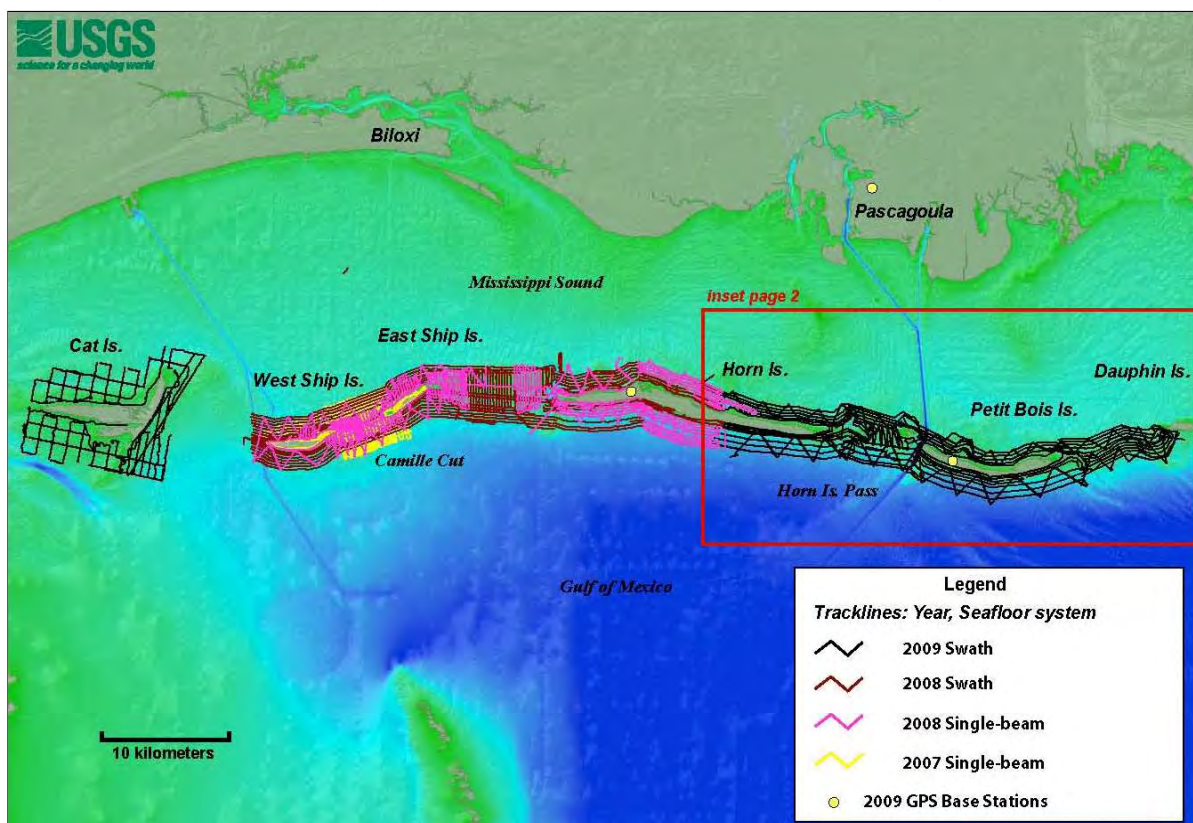

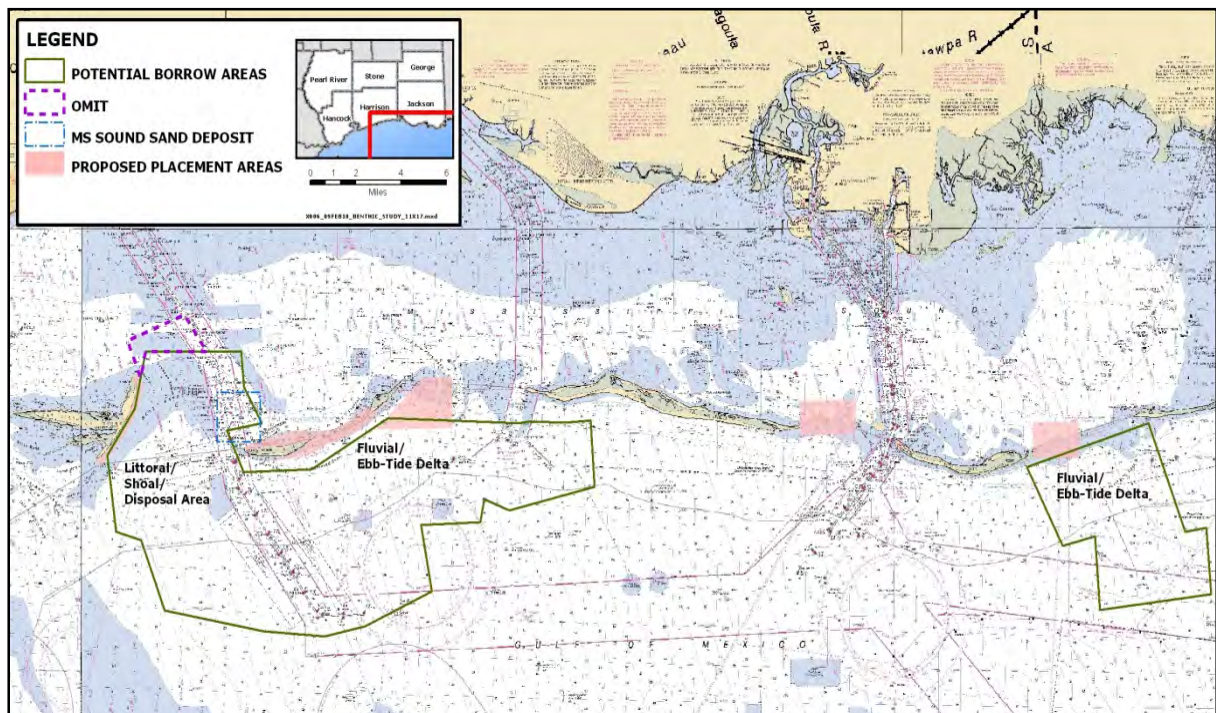

Figure 4.1.1 – Past geophysical surveys conducted by the USGS at Gulf Islands National Seashore.

In 2009, USACE entered into an Interagency Agreement with USGS to gain a better understanding of the availability of potential borrow areas containing suitable, high quality sand. This additional work would complement the ongoing USGS NGOM study effort by expanding survey data coverage beyond the Park's boundaries while incorporating USACE vibracore textural data to further validate and refine the geophysical interpretations. The overall intent was for the geophysical survey data to be collected by USGS and integrated with the vibracores collected by USACE "to

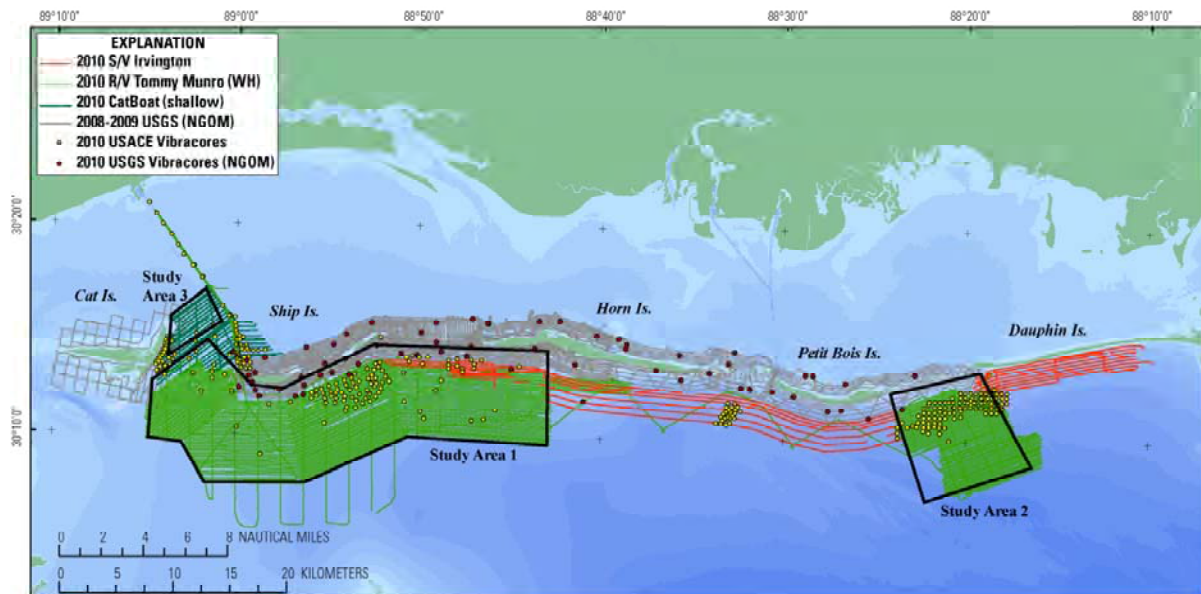

provide a detailed understanding of the regional shallow stratigraphy and the lithology of its various units” (Twichell et al., 2011).

Meetings between USACE and USGS led to the identification of areas of interest deemed to be geologically conducive to large sand deposits. Areas within the NPS boundaries were considered off limits. Figure 4.1.2 shows the areas selected for additional geophysical investigation by the USGS. These areas were not within park boundaries, but were adjacent to previous and ongoing investigations for the NPS.

**Figure 4.1.2 – Areas designated for geophysical survey to identify potential sand borrow sites.**

The entire region was then divided into three general Study Areas: seaward of Ship Island and Horn Island (Study Area 1); seaward of Petit Bois Pass (Study Area 2); and within Ship Island Pass, adjacent to Cat Island (Study Area 3). Figure 4.1.3 shows the Study Areas (black outlines), the tracklines of the geophysical surveys conducted by USGS for this study and the NGOM study, and the general location of the USGS and 2010 USACE vibracores.

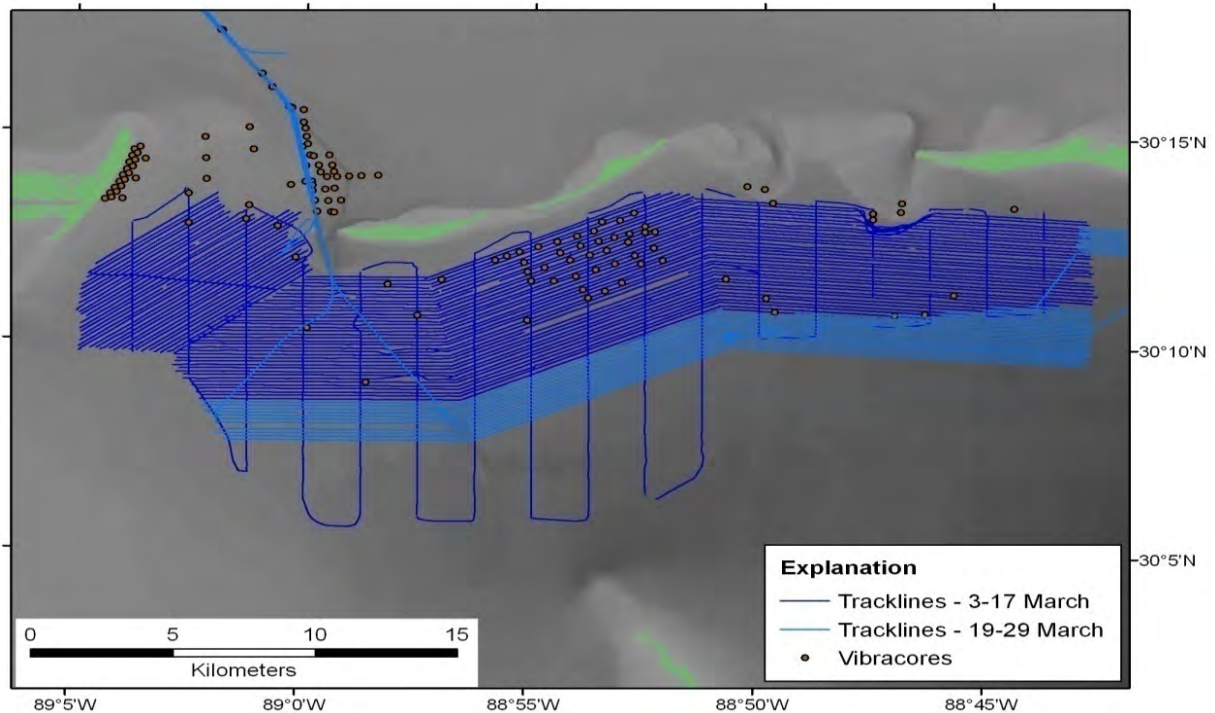

**Figure 4.1.3** Map showing the tracklines for geophysical data collected. Vibracores collected by USACE for the MsCIP project and the USGS for the Northern Gulf of Mexico (NGOM) project are shown. Main features were separated into three Study Areas (From Twichell et al. 2011).

#### 4.1.1 2010 SURVEY METHODOLOGY

In March of 2010, the USGS conducted two surveys covering approximately 300 square kilometers of the inner continental shelf offshore of the western Mississippi barrier islands, along the Gulfport Navigation Channel, portions of Mississippi Sound near Ship Island Pass, and south of Petit Bois Pass (Figure 4.1.1.1). The first survey cruise was conducted during March 3-17 and was staffed primarily by the Woods Hole Science Center. The second survey cruise was conducted March 19-29 and was staffed by USGS, St. Petersburg, FL. The University of Southern Mississippi's research vessel, *R/V Tommy Munro*, was used to collect the large offshore sections. In addition, the USGS research vessel, *R/V Gilbert*, a USGS 8-m Glacier Bay catamaran, surveyed the shallower Study Area 3, while the USACE survey vessel, *S/V Irvington*, assisted by surveying the nearshore area between Study Area 1 and 2 and east of Study Area 2. Much of this survey area abuts the seaward edge of a survey completed by the USGS in 2008 and 2009 (NGOM survey) and extends from 1 to 3 km seaward of the island chain, approximately 8 to 13 km offshore. Positions of the ship and geophysical data were determined using Differential Global Positioning System (DGPS) navigation, with an antenna mounted directly above the interferometric-sonar head on the starboard side of the vessel.

During acquisition, the survey vessels maintained speeds between 1.5 and 2.5 m/s (Twichell et al., 2011).

Study Area 1 was the largest study area. Data were collected along approximately 2,000 km of tracklines spaced approximately 150 m apart in the shore-parallel direction, and about 2 km apart in the shore-perpendicular direction as shown in Figure 4.1.1.1.

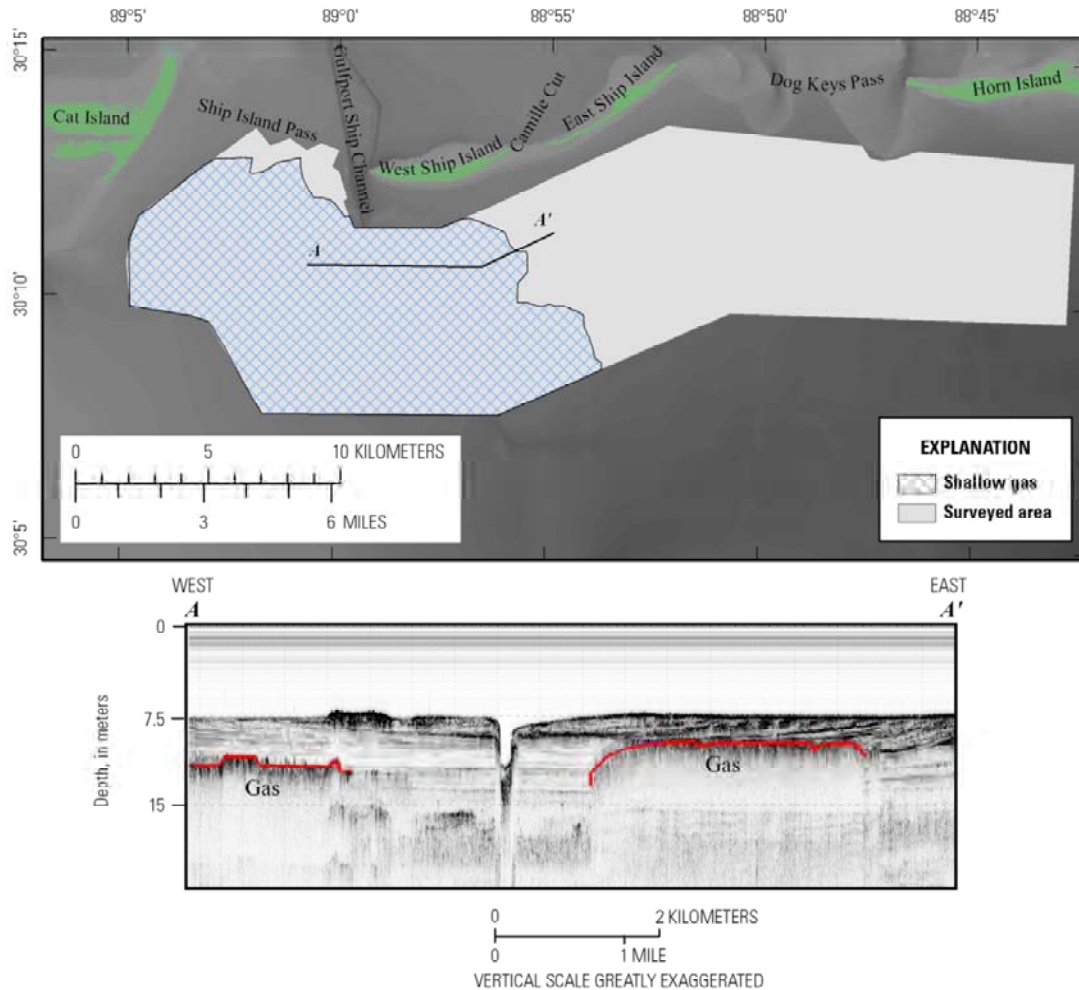

**Figure 4.1.1.1 - Tracklines along which geophysical data (CHIRP seismic-reflection, swath bathymetry, and sidescan sonar) were collected. Also, locations of vibracores collected by USACE.**

Shore-parallel, trackline spacing was chosen to ensure at least a 10% overlap of adjacent sidescan sonar swaths. The sidescan system produces a large swath width, typically between 150 and 200 m. Shore-perpendicular tracklines were used to facilitate internal comparison and correlation of bathymetric and CHIRP seismic-reflection data with shore-parallel versus shore-perpendicular orientations (Twichell et al., 2011). Interferometric-sonar, sidescan-sonar, and CHIRP seismic-reflection systems were deployed simultaneously during all the cruises. However, all three were not necessarily collected for the entire length of the tracklines. During the first leg of Study Area 1, interferometric-sonar, sidescan-sonar, and CHIRP seismic-reflection data were acquired along 1,321 km, 1,332 km, and 1,523 km of trackline,

respectively. During the second leg of Study Area 1, interferometric-sonar, sidescan-sonar, and CHIRP seismic-reflection data were acquired along 445 km, 455 km, and 492 km of trackline, respectively. Processed bathymetric soundings yielded a final bathymetric surface area of about 265 km<sup>2</sup>, which was gridded at a resolution of 50 m per pixel. The total area imaged with sidescan sonar was approximately 260 km<sup>2</sup> with gray-scale GeoTIFF images of the mosaics produced at 1 and 5 meter resolutions. Approximately 2,015 km of high-resolution CHIRP seismic-reflection profiles were collected. A 1,500 m/s speed of sound was used to convert the vertical scale of the seismic data from milliseconds of two-way travel time to depths in meters. Grid surface calculations were used to compute the thickness and volume of different stratigraphic units (Twichell et al., 2011). Gas was extensive in the sediment under much of the western part of Study Area 1 and limited interpretation of deeper horizons. Figure 4.1.1.2 shows an example of this phenomenon.

**Figure 4.1.1.2. Map showing the extent of the survey area affected by shallow gas (gray polygon) and an example profile showing the blanking of the deeper stratigraphy by gas (from Twichell et al., 2011)**

Data collection for Study Area 2 and 3 progressed in similar fashion. Further descriptions of the equipment, acquisition techniques, and data processing used in this survey are documented in Pendleton and others (2011), Forde and others (in press) and Pfeiffer and others (2011).

#### 4.1.2 CONCLUSIONS AND RECOMMENDATIONS FROM 2010 GEOPHYSICAL INVESTIGATION

At the conclusion of the March 2010 geophysical surveys, the USGS provided initial field interpretations of the survey data and also identified initial vibracore locations to gather physical samples of the sediments for inspection and textural classification to

validate their field interpretations. These recommendations were based on an area having the potential for large deposits of sand that could be economically dredged and used for the Barrier Island Project. Examples of the field interpretations are shown in Figures 4.1.2.1 and 4.1.2.2.

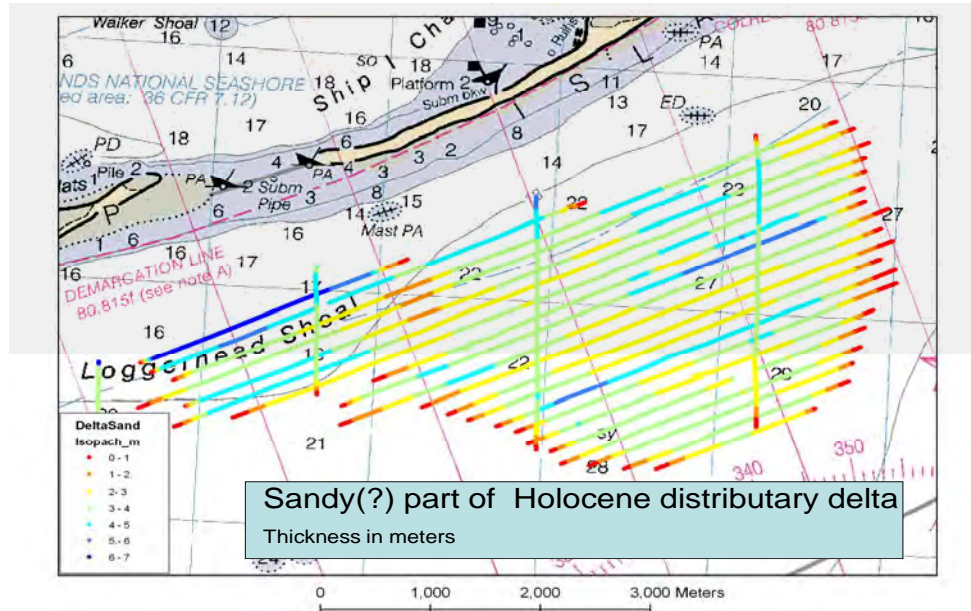

Figure 4.1.2.1 – Example isopach of area south of Camille Cut and East Ship Island designated as Ship Island study area, part of USGS' Study Area 1.

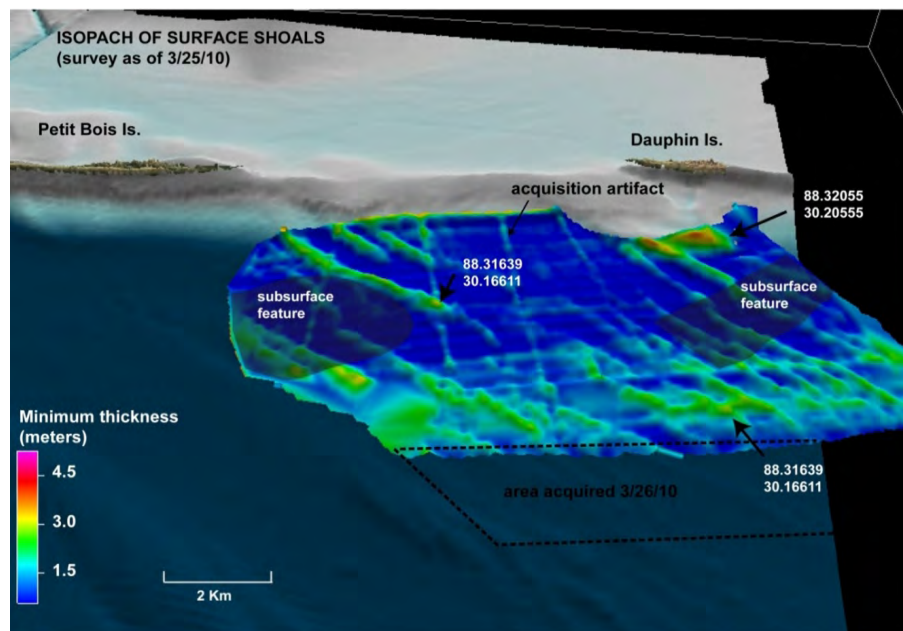

Figure 4.1.2.2 – Initial interpretation of geophysical data indicating sandy shoals south of Petit Bois Pass and designated as Petit Bois Pass study.

The USGS identified potential sand sources in the three study areas (Figure 4.1.2.3) and estimated quantities of useable sand in each one (Table 4.1.2.1).

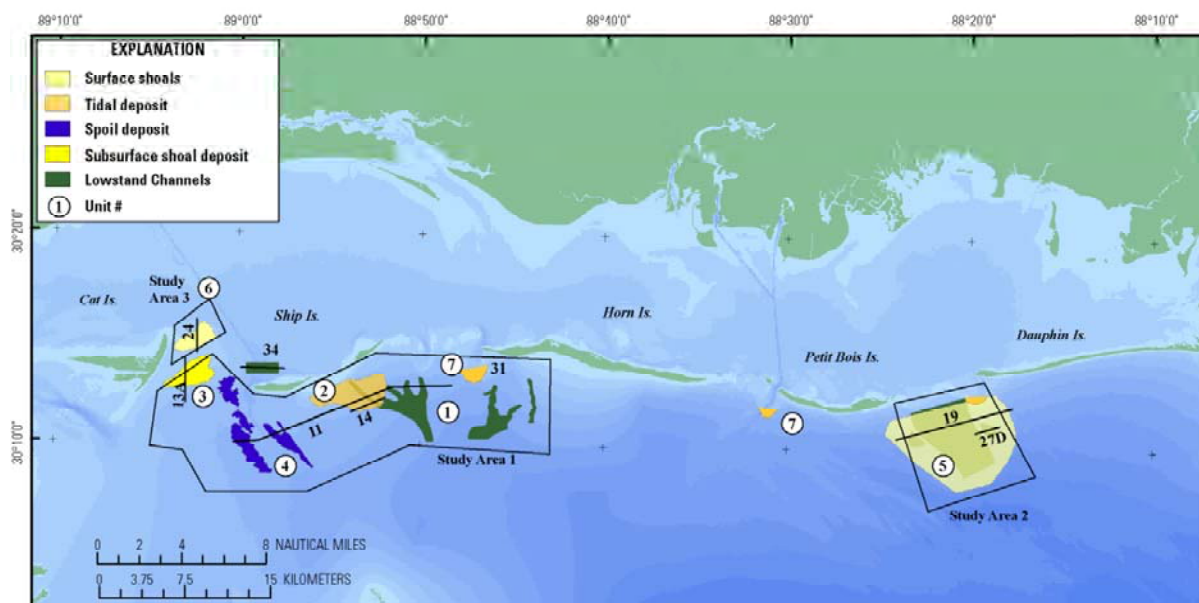

Figure 4.1.2.3 Locations of potential sand resources identified in this study. Each deposit is assigned a unit number that corresponds to textural information in Table 4.1.2.1 (from Twichell et al., 2011)

Table 4.1.2.1- Characteristics of potential sand-resource deposits located on the shelf offshore of the barrier islands south of the Mississippi coast. The unit number corresponds to the circled numbers in Figure 4.1.2.3. (Table 4.1 from Twichell et al., 2011)

Unit Number	Study Area	Deposit	Total volume ( $\times 10^6 \text{ m}^3$ )	Volume of deposit > 1 m thick ( $\times 10^6 \text{ m}^3$ )	Proximity to Camille Cut (km)	Sediment cover (m)	Median grain-size range (mm)	Estimated sand (%)

\* Volumes only for the part of the deposit within the Study Area.

While several recommended areas may contain potential borrow material, three primary areas were of interest because of their location, potential volume of the

available material, and habitat designation. These areas of interest were Cat Island, Ship Island, and Petit Bois Pass.

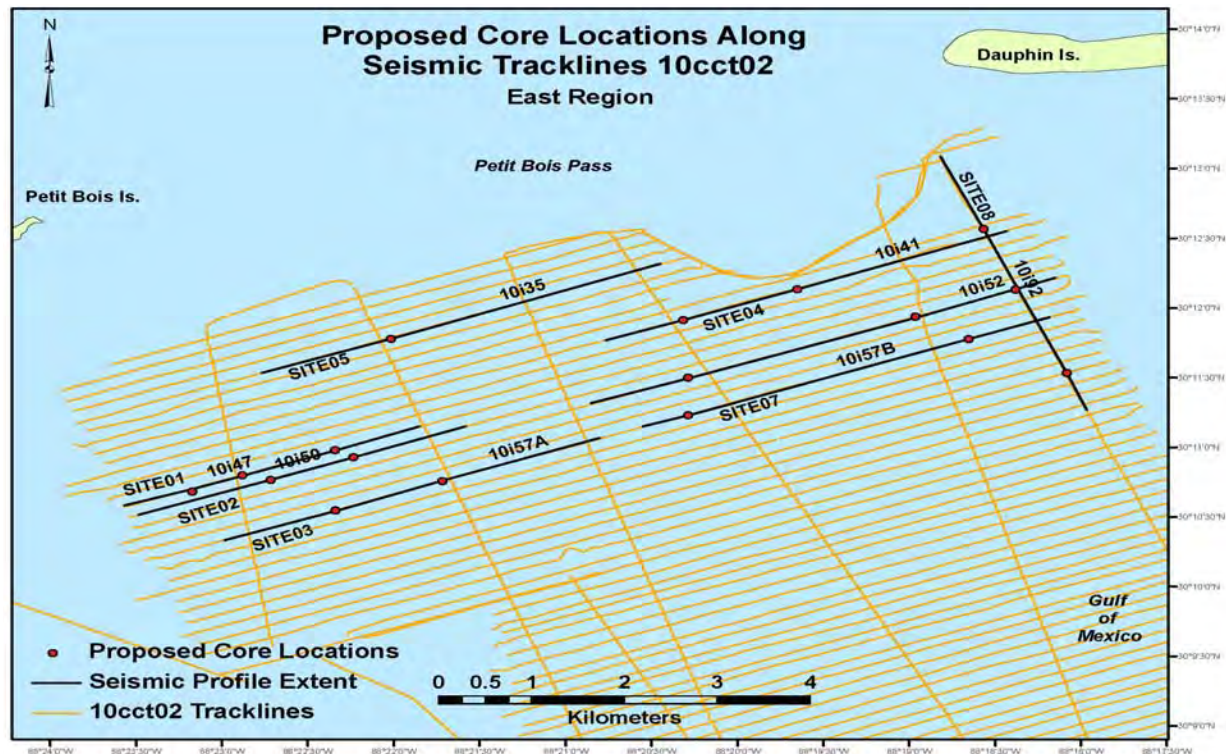

These locations were sampled with vibracores to obtain physical samples of the material to correlate with the geophysical data. Geologists classified the sediments and made initial observations of grain size and color. These vibracore locations covered several different areas near the islands, extending from near Cat Island (not within GUIs) eastward to Petit Bois Pass. This vibracore sampling is described in greater detail in Section 5.2. The westernmost area that was surveyed is shown in Figure 4.1.2.4, along with recommended vibracore locations based on initial field interpretation of the geophysical data. The recommended vibracores were used to determine textural characteristics of the different strata identified and validate the geophysical model. A separate layout of recommended vibracores was provided for the eastern portion that included the area south of Petit Bois Pass (Figure 4.1.2.5).

**Figure 4.1.2.4 – Initial field interruptions of geophysical data with recommended proof vibracore locations, western area of investigation**

The interpretations identified in Figures 4.1.2.2 and 4.1.2.3 were included in several different study areas. The buried shoal (#3) and dredge spoil deposits (#4) between Cat and West Ship Islands were included in the Ship Island Pass study area. The modern shelf (#7) and Holocene fluvial/deltaic deposits south of West Ship Island

(#2) were included in the Ship Island study area, and the remaining core sites to the east were all included in the Dog Keys Pass study area. Other study areas not identified as potential borrow sites, but falling within the limits of Figure 4.1.2.4, are Gulfport Channel, Mississippi Sound, and Dog Keys Pass. Figure 4.1.2.5 provides the recommended vibracore locations for Petit Bois Pass in Study Area 2.

**Figure 4.1.2.5 – Initial field interruptions of geophysical data with recommended vibracore proof locations, eastern area of investigation south of Petit Bois Pass.**

The shoals south of Camille Cut and the fluvial/deltaic deposit that lies south of East Ship Island represented the largest target areas for useable sand in Camille Cut and at East Ship Island. The deposit stretches along the front of East Ship Island for 9 km, is up to 5 km wide, and reaches 5.7 m in thickness. The deposit is 1.5 to 6 km from the Camille Cut restoration area. Seismic data show that this sandy deposit is exposed on the sea floor for much of its extent (Twichell et al., 2011). The dimensions of this deposit indicate it contains the required quantity of sediment for the Camille Cut area, while the geophysical interpretations, vibracores, and field classification indicate the material meets most of the proper criteria for restoration use. Unfortunately, lab data from the vibracores indicates that the sand is too fine-grained to be used in the core of the Camille Cut fill project, but could possibly be used as a capping material.

Another large deposit of interest was identified as Petit Bois Pass Shoals, shown in Figures 4.1.2.2 and 4.1.2.3. Flocks (2010) has described the features in this area as a combination of ebb tidal delta overlaying lowstand channel deposits. The fluvial deposits are not considered part of the ebb tidal delta and “do not contribute significantly to the littoral system that maintains the islands.” The shoal system and ebb-tidal delta contain > 90% sand. The delta contains moderately well-sorted, medium sand with a 2.3 - 4 m thickness. Removal of sediment within the inlet would likely “disrupt the littoral system”. The shoal systems, on the other hand, “do not contribute significantly to the littoral system”. The shoals contain poorly-sorted, medium sand and range in thickness from 2 - 5 m, surrounded by a 1 - 2 m mantle of poorly-sorted, silty sand. The shoal sands “originate from the same fluvial sources and are genetically related to barrier islands.” (Flocks et al. 2011) Based on these data interpretations and dimensions, the Petit Bois Pass is potentially a suitable borrow area.

Another area of interest for borrow was offshore from the east face of Cat Island. This area is within Ship Island Pass, but was given a separate study designation as the Cat Island study area. Although the geophysical surveys could not be performed in the shallow water of the study area, survey lines as completed in Ship Island Pass and other prior work by Otvos (1975) indicated that shoals in the Pass extend westward to Cat Island. Based on these previous studies and the USGS data interpretations, offshore of the east face of Cat Island was identified as a potentially good source for further investigation as a borrow site.

A final potential borrow area was identified from bathymetry work conducted as part of a separate sediment budget study. This study identified several mounds of sediments south of Horn Island Pass (the eastern-most #7 on Figure 4.1.2.3) that were located within a permitted offshore dredged material disposal area (Byrnes, oral comm.). These mounds were mostly sediments transported by littoral zone processes from Petit Bois Island, deposited in the Pascagoula Bar Channel, and then dredged and placed in the disposal area, thus creating the mounded features. Considering the source of the dredged material, this area was added as a sample area, designated as Horn Island Pass.

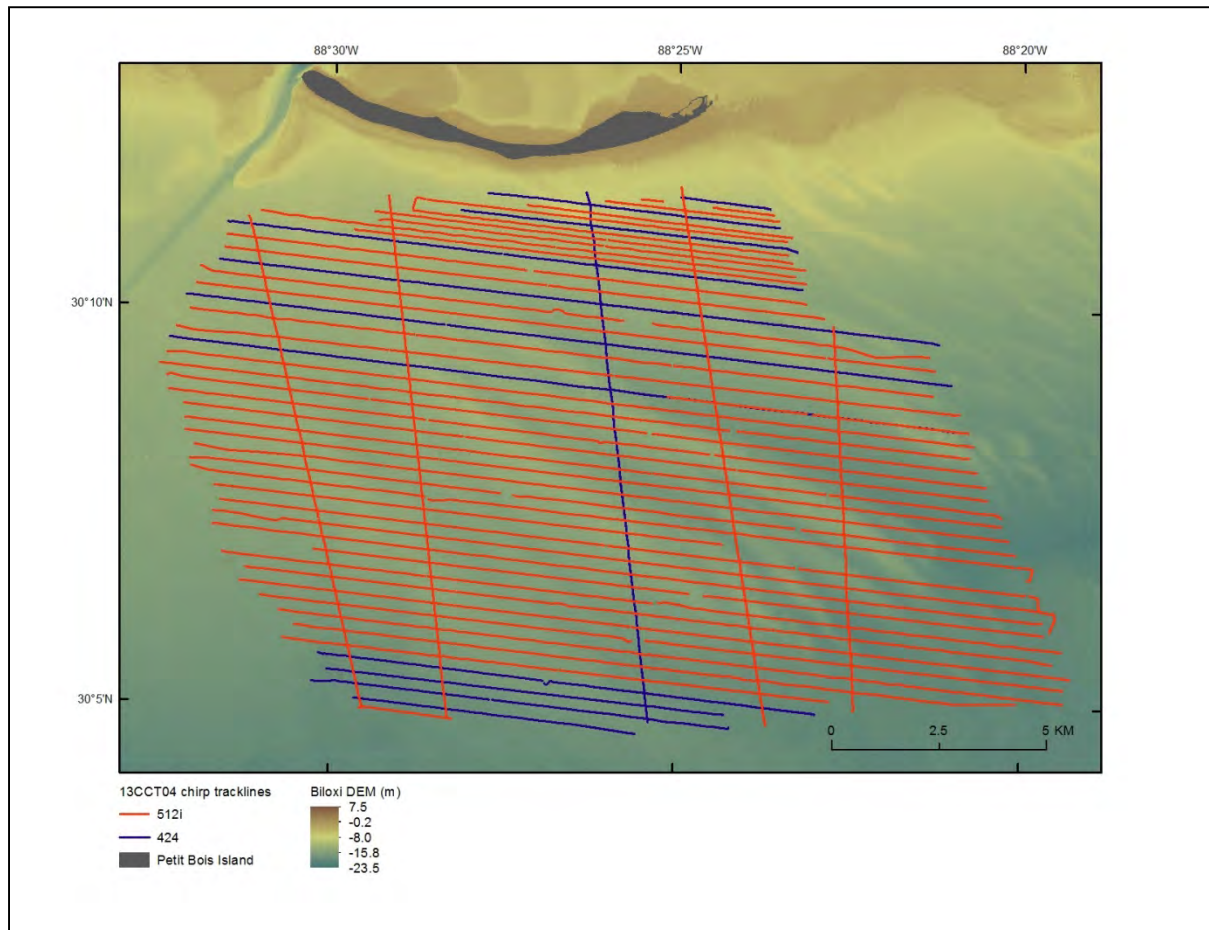

For a more detailed discussion of the 2010 surveys, see the USGS Open-File Report 2011-1173, The Shallow Stratigraphy and Sand Resources Offshore of the Mississippi Barrier Islands, (Twichell et al., 2011).

## 4.2 2013 GEOPHYSICAL SURVEY

Bathymetry for the area south of Petit Bois Island, and adjacent to the eastern edge of the geophysical survey from 2010, indicated several large shoals that might offer suitable sediment in economical quantities. Unfortunately, there was no current geophysical data for this area to confirm this supposition. This data gap led to USACE entering into another Inter-Agency Agreement with USGS to conduct a geophysical survey similar to the 2010 surveys, with the purpose of gathering data to conduct a stratigraphic and morphologic assessment south of Petit Bois Island and to identify core locations in support of the USACE sediment sampling strategy.

The survey was conducted in August 2013 and covered a region approximately 1 km to 13 km offshore of Petit Bois Island and approximately 77 miles<sup>2</sup> (212 km<sup>2</sup>) in area (Flocks, 2014). The survey equipment used and the data collected was the same as for the 2009-2010 surveys. The University of Southern Mississippi's research vessel *Tommy Munro* was the platform used to conduct the surveys. Line spacing of the tracklines was 150 m in waters less than 15 m, and 300 m in deeper waters, oriented parallel to the shoreline. Five shore-perpendicular tracklines were collected across the survey area to tie the horizontal lines together. Data collected included DGPS navigation, high-resolution CHIRP seismic-reflection profiles for mapping the shallow stratigraphy, interferometric swath bathymetry to provide a detailed understanding of the seafloor morphology, and sidescan sonar imagery for mapping the seafloor geology (Flocks, 2014). Figure 4.2.1 shows the area surveyed and the completed survey tracklines described previously.

**Figure 4.2.1 – 2013 Geophysical Survey tracklines. Petit Bois Island is directly to the north. (Flocks, 2014)**

The USGS used the survey data to create a sand isopach map for the surveyed area, incorporating the surface and subsurface features, and outlining the thickest shoals (Figure 4.2.2) for sampling. The black dotted lines trace the shoal boundaries. The thickness of the shoals and sand sheets is represented by red (thickest deposits) and grades to blue (thinnest deposits).

Figure 4.2.2 Isopach map of surface sediments show shoal systems extending NW-SE across study area surrounded by a thin (<1.5 m) sand sheet. Base of surface sediments is defined by the top of the Holocene transgressive deposits (Flocks, 2014).

#### 4.2.1 Results of the 2013 Geophysical Survey

The results of the 2013 survey and subsequent study indicate that the shallow stratigraphy of this region is the product of fluvial-marine sedimentation, driven by sea-level oscillations during the late Pleistocene and into the Holocene (Flocks, 2014, and, Flocks and others, 2011b). The predominant sea floor features include shoals and shelf sand sheets of various sizes and orientations. The inner shelf is mainly covered by flat sand sheets that grade laterally into muds within the inner shoal areas. In profile, the shoals are the predominant vertical features in the area (Flocks, 2014). The seafloor within the study area slopes to the southeast with gradients generally about 0.03 degrees, which is generally consistent with the Mississippi-Alabama shelf within 20m of water (Flocks, 2014). Three major NW-SE trending shoals run through the study area (Figure 4.2.1.1), with side angles ranging from 0.07 – 0.35 degrees, with the shoals adjacent to the large inner-shoal area in the eastern half of the survey area (Figure 4.2.2) having the highest gradients (Flocks, 2014). The major subsurface geology includes Holocene and Pleistocene-

age features such as bayhead delta deposits and marine-transgressive deposits infilling older fluvial distributary systems (Flocks, 2014). Figure 4.2.1.1 shows the refined location of these major features. Because these shoals are in deeper water, they are generally more stable features than ones in shallower waters. This study area dovetails in with the 2010 geophysical survey area south of Petit Bois Pass and indicates that the area is divided between fewer larger shoals in the west and smaller, more numerous shoals in the east. The dividing intershoal area also contains sand, but in thinner, surficial deposits (Table 4.2.2). Table 4.2.1.1 contains the estimated volumes, thicknesses, grain size, and sand content for these major features.

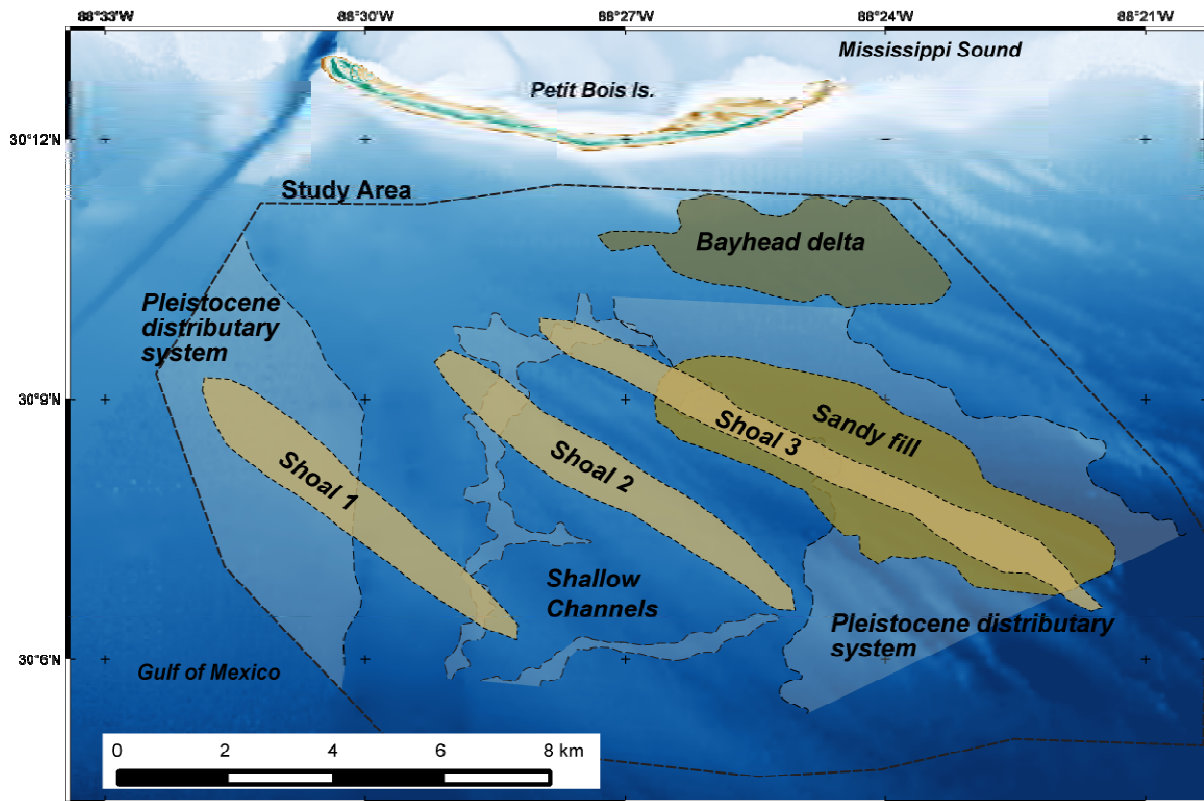

Figure 4.2.1.1 Significant features identified in the USGS's study include shoals and fluvial deposits (Flocks, 2014)

**Table 4.2.1.1. Physical characteristics of features identified in the study, the study area, and neighboring Petit Bois Island for comparison (Flocks, 2014).**

<sup>4</sup>Grainsize analysis from USACE 2014. Bayhead delta grain size analysis from Kelso and Flocks (2014).

USACE personnel used the shoal outlines and suggested initial vibracore locations as guides to develop a vibracore layout for the 2013 geotechnical sampling event. Because of the relatively thin sand sheets between the shoals and throughout the study area, the thickness and composition of the three shoals made them the primary targets for core sampling by USACE. Other core sites were suggested by USGS to identify potential subsurface deposits, too. The large subsurface sandy fill deposit in Figure 4.2.1.1 was not initially identified before sampling began, but the vibracore layouts were readjusted to sample this new area after it was identified by USACE vibracores and verified in the USGS's geophysics.

For a more detailed discussion of the 2013 survey, see the USGS's report, *Near-surface stratigraphy and morphology, Mississippi inner shelf, northern Gulf of Mexico*. (Flocks and others, 2014).

## 5.0 GEOTECHNICAL SAMPLING

Sediment sampling events were conducted in 2010, 2011, 2012, and 2013. The vibracoring method was selected to collect the sediment samples for the geotechnical investigation because it works well in unconsolidated, granular material and produces a minimally-disturbed sediment core relative to other sampling techniques. It is especially useful in a marine environment where it can be difficult to maintain a stationary position for extended periods of time for other sampling techniques. The following paragraphs provide a brief summary of each sampling event.

The 2010 sampling event included all recommended vibracore sites identified by the USGS' initial field interpretations of the geophysical survey data collected in 2010. This phase of sampling consisted of 369 vibracores and included sites from Cat Island eastward to Petit Bois Pass. A site south of Horn Island Pass was also included after results from the sediment budget study indicated that a potential deposit of sand was located there. This sand is a historical disposal site where dredged sediments from the Pascagoula Bar Channel were placed.

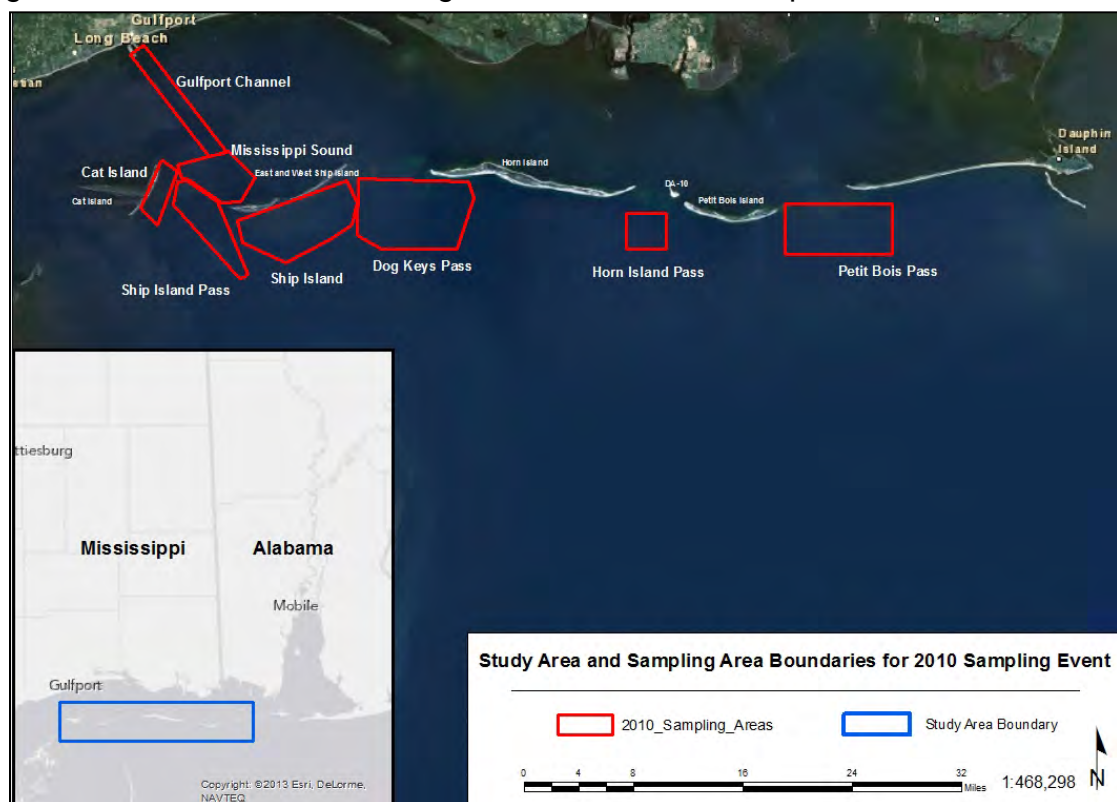

Figure 5.0.1 – 2010 Sampling Areas.

The 2011 sampling event was performed during the summer of 2011. The purpose of this sampling event was to fill data gaps for the Cat Island and Petit Bois Pass-Alabama investigation sites, and to obtain data on an active dredged material disposal site for the Pascagoula Bar Channel running through Horn Island Pass, designated as Disposal Area 10 (DA-10), and known locally as Sand Island. This phase of sampling consisted of 89 vibracores and included sites from Cat Island, DA-10, and Petit Bois Pass. The initial borrow site proposed for Cat Island had negative findings based on modeling of wave-focusing caused by the excavation of the borrow material. Three other sites were proposed, but none were recommended because of a lack of sufficient vibracore data. Vibracores were added to obtain the data needed, but then these three sites were eliminated because of the vibracore data. However, these results did lead to a revised potential borrow site designated as Cat Borrow Site 4, considered the best alternative. In the east, vibracores were added to the existing array at Petit Bois Pass-Alabama to further delineate the proposed sites identified in 2010. The last site investigated during 2011 was at DA-10 where there was no available vibracore data other than old Pascagoula Bar Channel vibracores. The results of the sediment budget modeling report (Byrnes, et al., 2011), showed that the disposed sediment was placed too far north in the pass for longshore currents to transport it downdrift to feed the other islands as initially intended when it was designed. This lack of movement made the man-made island a viable sand source because the sand was not going to be taken out of the littoral system, merely moved downdrift. Therefore, removal of the sand would not be interfering with the littoral system as a whole.

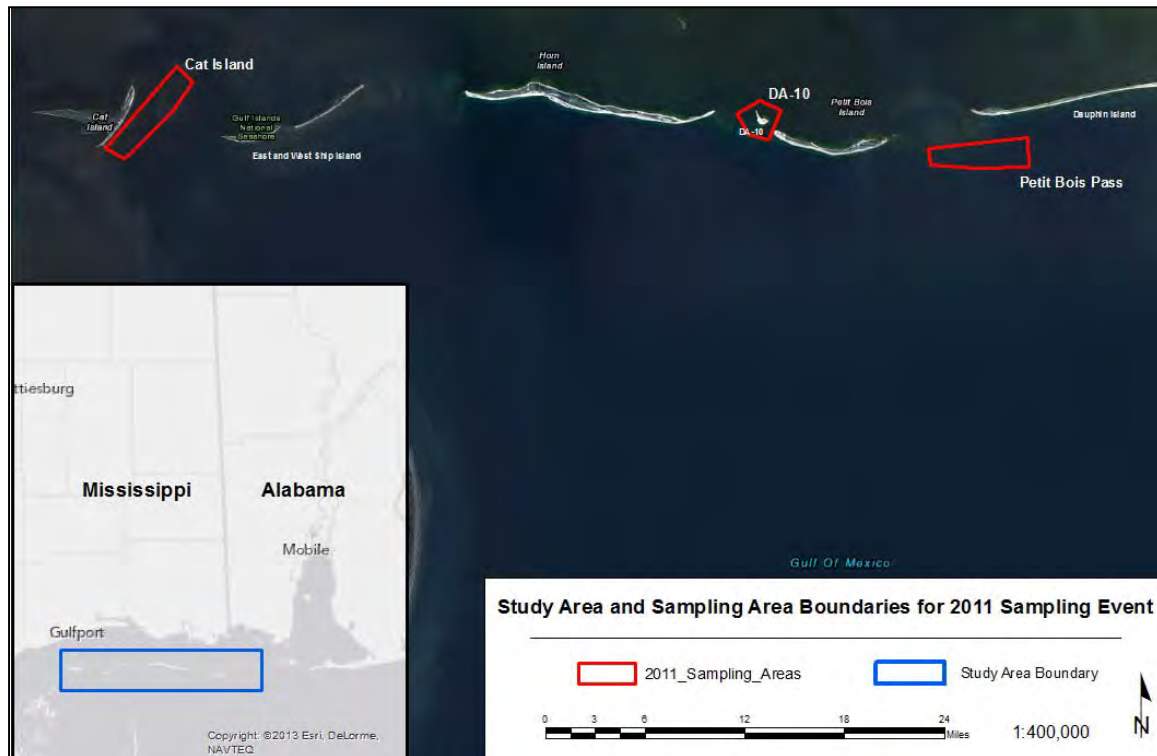

Figure 5.0.2 – 2011 Sampling Areas.

The 2012 sampling event was conducted from November 2012 to January 2013. This sampling event consisted of 230 vibracores in Horn Island Pass, Petit Bois Pass-Alabama, Petit Bois Pass-Mississippi, and Petit Bois Pass-Outer Continental Shelf (OCS). This event collected more samples in the Horn Island Pass area to further delineate the dredge-disposal mounds and to determine if the margins of the Pascagoula Bar Channel contained suitable sediment for use in this project. Sampling was conducted south of the eastern end of Petit Bois Island to determine the sediment characteristics of a large northwest-southeast-trending shoal located outside the NPS boundary in Mississippi state waters. Additional vibracores were drilled around the Petit Bois Pass-Alabama borrow areas identified in the 2010 and 2011 sampling events to determine the feasibility of expanding their boundaries out further. Vibracores were also drilled in an area 5 miles south of Petit Bois Pass, targeting several shoals identified during the 2010 geophysical survey.

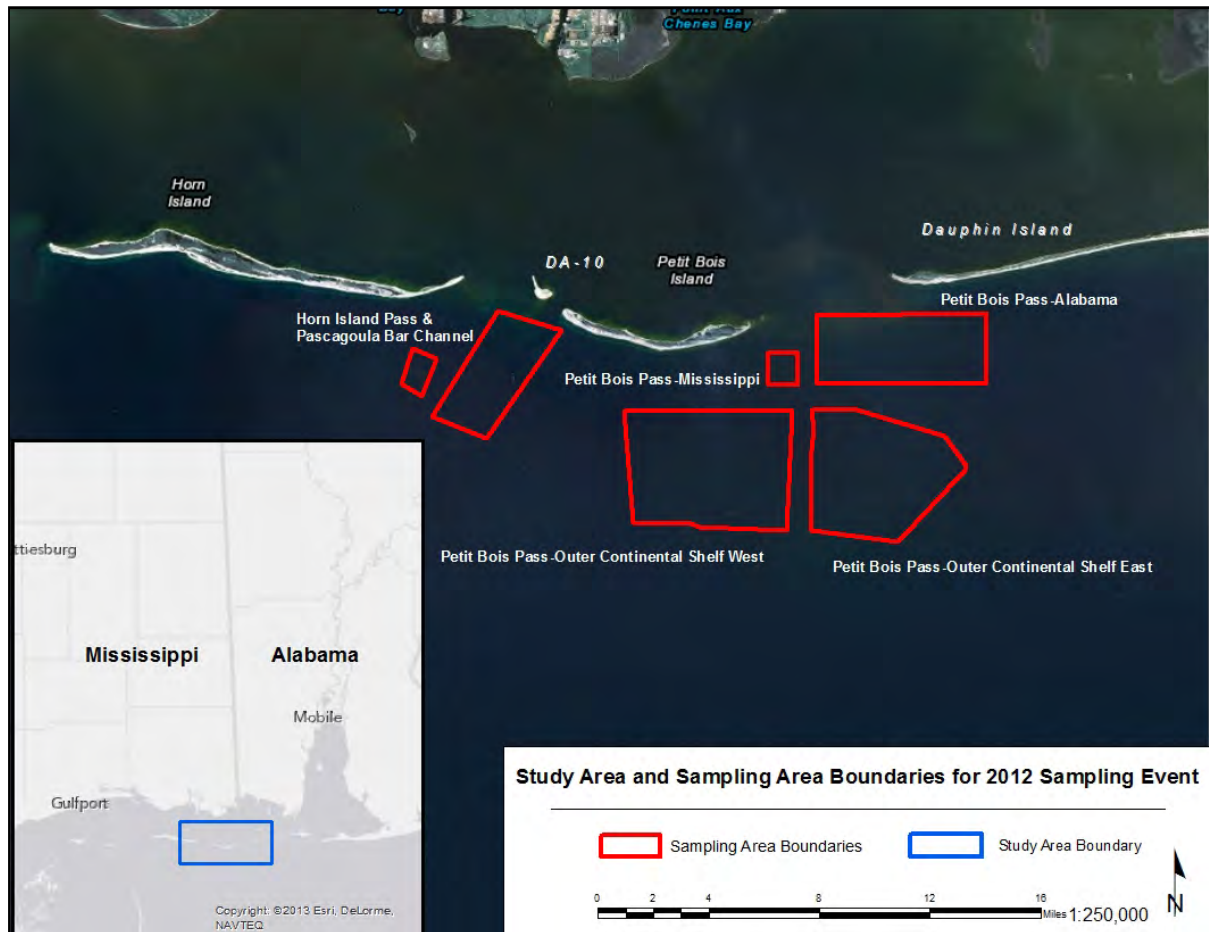

Figure 5.0.3 – 2012 Sampling Areas.

The 2013 sampling event was conducted from 22 November 2013 to 22 February 2014. It consisted of 206 vibracores in the area south of Petit Bois Island and in the southern reach of Horn Island Pass. The Horn Island Pass vibracores were conducted to further delineate borrow areas previously identified on the dredged disposal mounds during the 2012 sampling event. The Petit Bois Pass-OCS vibracores targeted the large shoals identified during the 2013 geophysical survey on the western side of the area and also augmented vibracores in the eastern portion of the area from the 2012 sampling event.

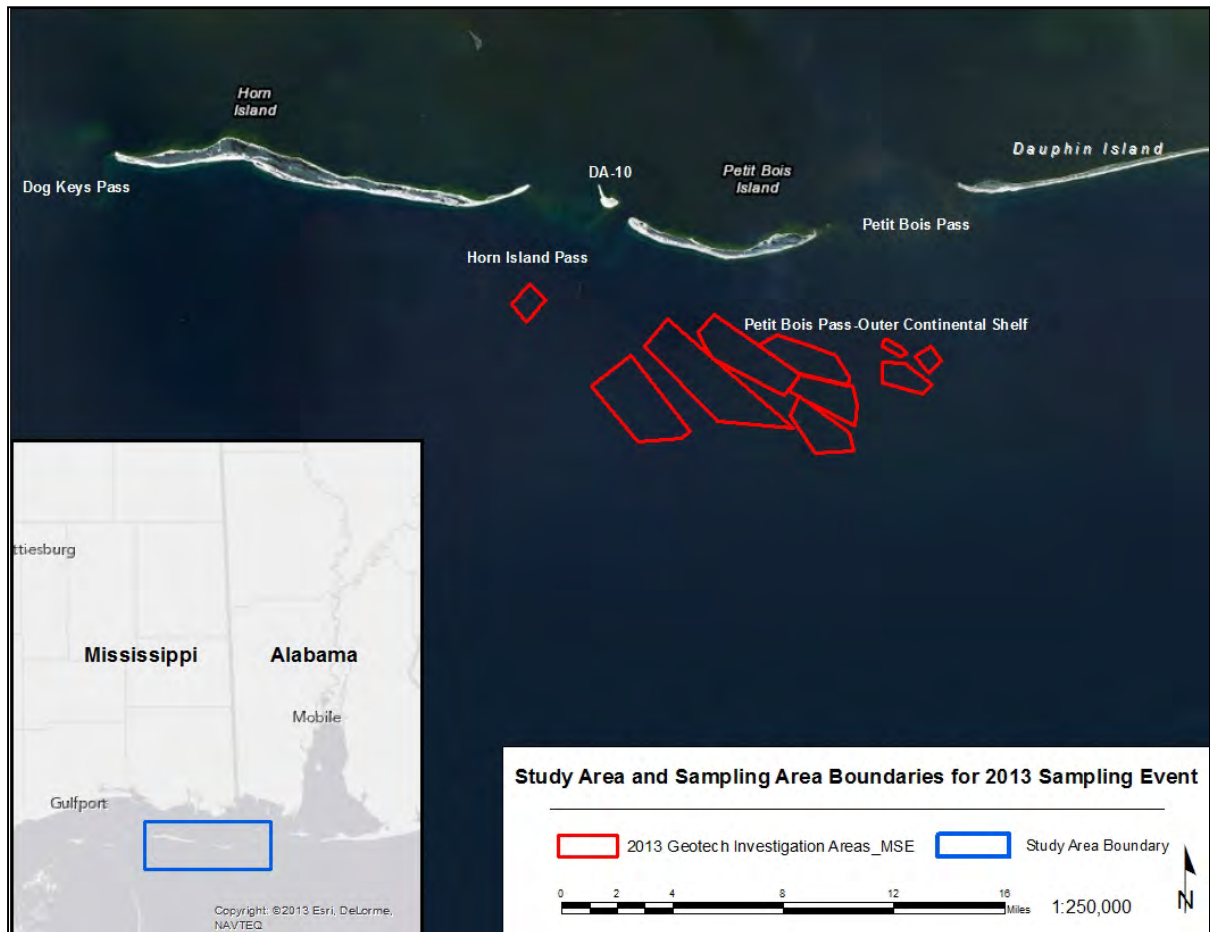

Figure 5.0.4 – 2013 Sampling Areas.

Figure 5.0.5 is a consolidated map view of the actual vibracore locations from the 2010-2013 sampling events. Each sampling event is color-coded to show the temporal and spatial extent of sampling throughout the four-year investigation.

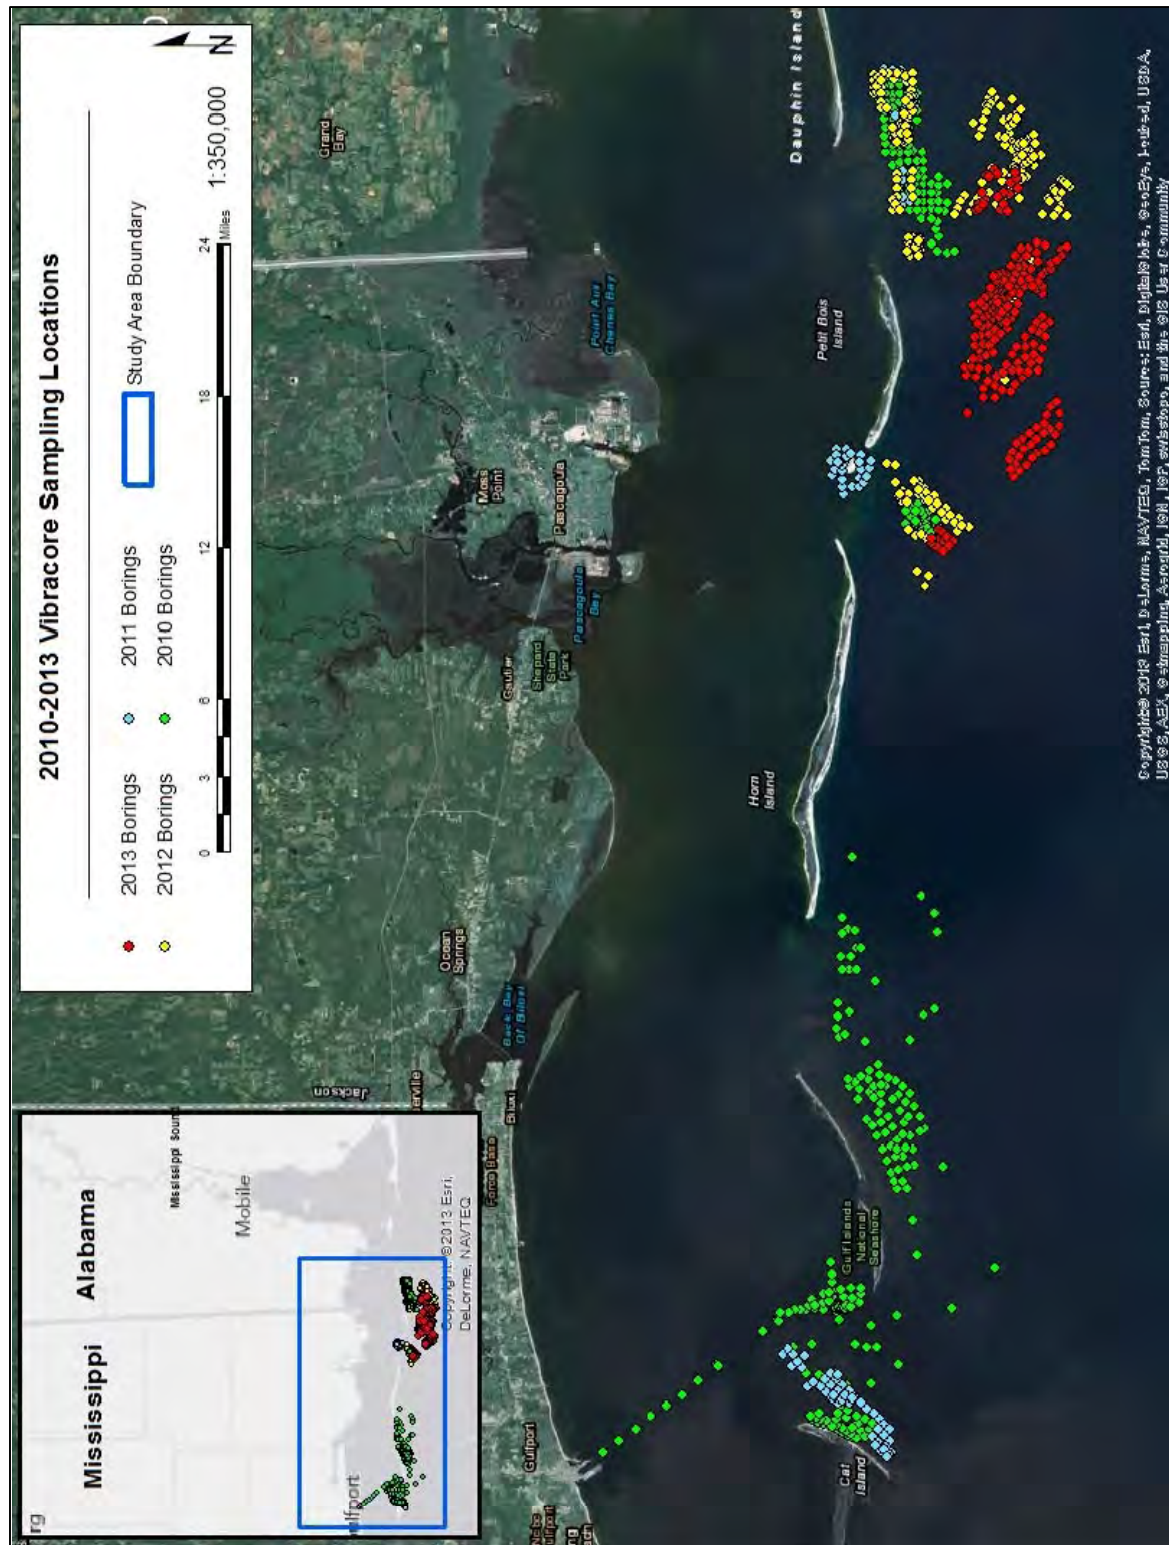

Figure 5.0.5 – Locations of vibracores completed for the 2010-2013 sampling events.

## 5.1 VIBRACORE SAMPLING PROCEDURES AND PROTOCOL

Geotechnical sampling was conducted using a vibracore sampler with a 20-foot core barrel. Photographs of the operation with the vibracore sampler used for the 2010, 2011, and 2013 sampling events are shown in Figures 5.1.1, 5.1.2, and 5.1.3. Figure 5.1.1 is the vibracore unit lying on its side on the deck of the vessel used during sampling in 2010, 2011, and 2013. The red unit at the top of the vibracore barrel, to the right side of the photograph, is a hydraulically-driven concentric motor. When in operation, the motor produces a high frequency, low amplitude vibration that is transmitted through the attached 20-foot core barrel, shown in the photograph. This barrel runs vertically through the center of the derrick's four legs and the center of the base plate. The vibracorer used for the 2012 sampling event was different in its design, but the same principles apply. The core barrel has an inner sleeve constructed of clear plastic that is inserted prior to sampling and is held in place by a stainless steel shoe that screws onto the bottom of the core barrel. A metal catcher is also placed in the end of the sample tube, prior to the shoe being screwed on. It prevents the sample from falling out of the barrel as the barrel is lifted from the seafloor. The entire unit is lifted from the deck by a crane, or an A-frame with winch, and lowered into the water until its four foot pads are resting on the sea floor (Figure 5.1.2).

Figure 5.1.1 Vibracore unit used for 2010, 2011, and 2013 sampling events.

**Figure 5.1.2** Vibracore unit being deployed during the 2012 sampling event.

The vibratory motor is activated and the vibrations transmitted down the barrel cause liquefaction of the sediments. Gravity pulls the core barrel down through the sediment. A core of the sediment slides up into the inner sleeve as the core barrel penetrates the underlying formation. This 20-foot penetration usually takes less than 60 seconds. When full penetration is complete, or the barrel will not penetrate any further, the unit is shut down. The vibratory unit is lifted first, pulling the core barrel up with it. When the vibratory unit slides to the top of the derrick, the entire unit is then lifted back onto the deck and laid on its side. The shoe is removed and the plastic inner tube containing the sample can be removed. After the plastic sample tube is removed from the core barrel, it is laid on a table, the metal catcher is removed from the bottom end, and the plastic tube is sawed open longitudinally with a circular saw to expose the entire sediment core. The size of the sampling vessel dictated how the sample was opened. For the 2010, 2011, and 2013 sampling events, the vessel was large enough to cut the entire 20-ft tube longitudinally and keep the sample relatively intact (Figure 5.1.3). The 2012 vessel was smaller and the tubes were cut into 4 5-ft sections and then cut longitudinally for access to the sediment (Figure 5.1.4).

Figure 5.1.3 20-ft vibracore tube cut longitudinally for inspector to sample sediment during 2013 sampling event.

Figure 5.1.4 Vibracore tube cut into 4 5-ft sections and then longitudinally for logging during 2012 sampling event.

A USACE geologist or geotechnical engineer conducted the sampling for the 2010-2013 sampling events. During the 2010 sampling event, the NPS had geologists or geotechnical engineers on the vessel during all sampling to make field determinations of the material. A protocol was established to streamline the sampling effort as much as practicable. Each vibracore was photographed and then classified using visual-manual techniques (ASTM D2488) by the drilling inspector in its entirety. Geotechnical lab testing (ASTM D2487) was conducted only on sediment samples that were perceived by the on-site geologist to be of potentially suitable material for project use. Therefore, some vibracores did not have any geotechnical testing conducted on the recovered material other than the geologist's visual-manual field classification. Recoveries that included thick clay or silt strata were typically disregarded for sampling. Bag-samples for laboratory testing were extracted from the core at selected intervals depending on field-estimated textural characteristics. Sands, ranging from silty sands (SM) to poorly graded sands (SP), were bag-sampled, while clays (CL and CH) and silts (ML and MH) were discarded. The USACE inspector had the discretion to not sample sandy material that did not appear to be suitable either because of its dark color or because of its fines content. This eliminated some SM material and most clayey sands (SC). If a two-foot or greater thickness of clay or silt was in the vibracore, deeper material below it was generally not sampled. These thick clay or silt layers were used as a basement cutoff because of the difficulty in dredging through them and their effect on sediment quality control at the placement site.

For potentially suitable samples, a commercial laboratory conducted a mechanical sieve analysis on the sediment using the following sieve sizes: 0.375-in., Standard U.S. #4, #10, #20, #40, #60, #100, and #200. A cumulative grain size distribution curve was created by plotting the percentages of the dry weight sample retained on each sieve size (Y-axis, linear scale) versus the sieve size (X-axis, log scale) and then drawing a best-fit curve through these data points (Figure 5.1.5). Grain size distribution curves were plotted for almost all sediment samples collected on the islands and all the offshore samples. The following statistics were determined or calculated from information on the curve: the median (D<sub>50</sub>), the graphic mean, the coefficient of uniformity (C<sub>u</sub>), and the coefficient of curvature (C<sub>c</sub>).

Figure 5.1.5 Example gradation curve showing the graphical determination of the D60, D50, D30, and D10 values.

The median grain size by weight, or D50, means that half of the sample is coarser and half of the sample is finer than this grain size. It is taken straight from the gradation curve. See Figure 5.1.5.

The graphic mean,  $(D_{84} + D_{50} + D_{16})/3$  (substituting the  $D_{15}$  and  $D_{85}$  values for the  $D_{16}$  and  $D_{84}$  values in the formula), was calculated for each sample to compare with the D50. The graphic method of computing the mean reduces much of the sampling and testing errors associated with calculating the mean statistic because it discounts the bottom 16% fine fraction and top 16% coarse fraction of the sample curve (in this case the top 15% and the bottom 15%) which are generally susceptible to error and might otherwise skew the statistic (CEM, 2008). In a normal distribution, the median and the mean are equal. However, generally with sediments these two statistics are not the exact same because the grain size distribution is not exactly normal. For this

study, the D50 statistic for each sample was almost always slightly finer than the graphic mean statistic.

The coefficient of uniformity,  $C_u = D_{60}/D_{10}$ , measures the particle size range within the sample. The smaller the  $C_u$ , the steeper the gradation curve because it contains a smaller range between the  $D_{60}$  and  $D_{10}$  values (Figure 5.1.5). The smallest  $C_u$  value is 1, which would indicate a sediment with the same grain size throughout. This would be shown as a completely vertical curve on the graph. For sand, a  $C_u$  value greater than 6 indicates a non-uniform size range, or well-graded distribution, where the  $D_{10}$  is much smaller than the  $D_{60}$ . This is represented on the graph with a more gentle slope (Curve 1, Figure 3.1.2.2). There were no samples collected with a  $C_u$  greater than 6.

The coefficient of curvature,  $C_c = (D_{30}/D_{10}) / (D_{60}/D_{30}) = D_{30}^2 / (D_{10} \cdot D_{60})$ , is a measure of the symmetry and shape of the gradation curve, and compares the slope of the curve representing the finer particles ( $D_{30}/D_{10}$ ) with the slope of the curve representing the coarser particles ( $D_{60}/D_{30}$ ). The minimum value of  $C_c$  is 1 and occurs when all sizes contributing to the  $C_u$  are about equally represented. As the coefficient of curvature increases, the smaller particle size content increases and becomes more influential on the engineering properties of the sediment. A value from 1 to 3 indicates a well-graded sample. A sediment sample's  $C_u$  and  $C_c$  are both used to determine if it is poorly graded or well-graded. Only poorly graded sands were found during the investigation.

The percentages of coarse, medium, and fine sand were calculated, in addition to the percentage of fine material (clays and silts) passing through the #200 sieve. A USCS classification and material description were assigned to each sample. For the 2010-2012 sampling events, qualitative wet and dry Munsell Color classification and grain angularity classification were conducted by Mobile District personnel with aid from the NPS. The 2013 sampling event was evaluated by USACE's Savannah District Materials Testing Lab during their grain size testing. The drilling inspector completed a SAM FORM 1836-MsCIP (Drilling Log) for each vibrocore using Bentley's gINT V8i software. The final logs include both the field classification and the laboratory classification for the samples, lab data ( $D_{50}$  and percent fines), the Munsell Color Classification, and estimated seafloor elevation.

Water depths at the site of sampling were taken using the sampling vessel's fathometer. These water depth readings were converted later to elevations using local NOAA tidal gauge data for the date/time that the sample was taken. Because of the potential for error with this method, all potential borrow areas will be surveyed by a USACE hydrographic survey vessel as part of the plans and specifications process to verify seafloor surface elevations and make adjustments to the borrow area cut elevations as necessary.

Due to the lag time between collection of samples and return of lab results, decisions had to be made as to the potential suitability of the sand for use in the project based on its initial field classification. If the quality of the sand was deemed suitable by the inspector, the limits of the area defined by the geophysical survey were gridded with holes to better delineate the deposit and to provide samples for textural classification. If the initial cores did not contain suitable sand, that area would not receive any additional coring investigation. This technique was used throughout the four sampling events to be as efficient with coring as possible.

Appendices B through L contain the gINT-generated drilling logs for each vibracore, followed by the respective laboratory testing worksheets as applicable. Each appendix also contains a consolidated listing of each sample taken from the cores for laboratory testing in that particular area, along with its relevant statistics.

Once the final drilling logs were completed, an analysis was conducted to begin delineating potential borrow areas. If the vibracore samples in an area did not show any potential for use as a borrow area, either because the material was unsuitable or the distribution of the suitable material was too thinly bedded or too widely dispersed to design an effective borrow area, that study area was discounted. For remaining borrow areas, initial rough order of magnitude volume calculations were performed to ensure that enough suitable material was available in the area to make it economical for mining. Wave modeling and hydrodynamic modeling were conducted for potential borrow sites that were in areas of shallow water or contained features that might be affected by the removal of the material. Borrow area shapes and cut depths were refined, taking into account bathymetry, sediment thickness, hydrodynamic, archaeological concerns, and potential dredge equipment types, to optimize the mining of the suitable material for the borrow areas. This refinement has led, in most cases, to a reduced quantity of available material from the initial

USGS estimates. The borrow area statistics in Section 6.0 are based on these updated borrow area designs.

**5.2 INVESTIGATION AREAS AND INITIAL FINDINGS**

The following sections discuss the results from the 2010-2013 sampling events organized by investigation area.

**5.2.1 GULFPORT CHANNEL INVESTIGATION AREA**

The sediments along the sides and below the bottom of the Gulfport Navigation Channel were sampled to determine if their material could be used as a borrow source if the channel is widened or deepened in the future. Previous investigations of the channel have included numerous vibracores to characterize the sediments as part of channel dredging operations. Twenty-nine (29) 2010 vibracores were completed along the channel alignment for this project. Of these 29 vibracores, eight (8) vibracores were initially positioned based on the results of the USGS' geophysical survey. The results of the new vibracores indicated that very limited amounts of sand were located over scattered areas. Most of the sediments observed in the samples contained silts or clays and would not be useful for the project. Another fifteen (15) vibracores were cored in one selected area based on data obtained during a geotechnical investigation for the existing channel alignment. The final six (6) vibracores were cored near the Gulfport Harbor to verify that sediment composition in that area was not suitable for beneficial use. This material was too fine-grained for the project. Unfortunately, the vibracores did not indicate suitable material in large enough quantities for use in the project. The general layout of the vibracores completed for Gulfport Channel is shown in Figure 5.2.1.1. The table in Appendix B provides the coordinates of the vibracores, the Unified Soil Classification System designation of the sample, the Munsell Color designations for wet and dry samples, and data from the laboratory gradation analyses. Additional information, including drilling logs and full gradation information, is included in Appendix B.

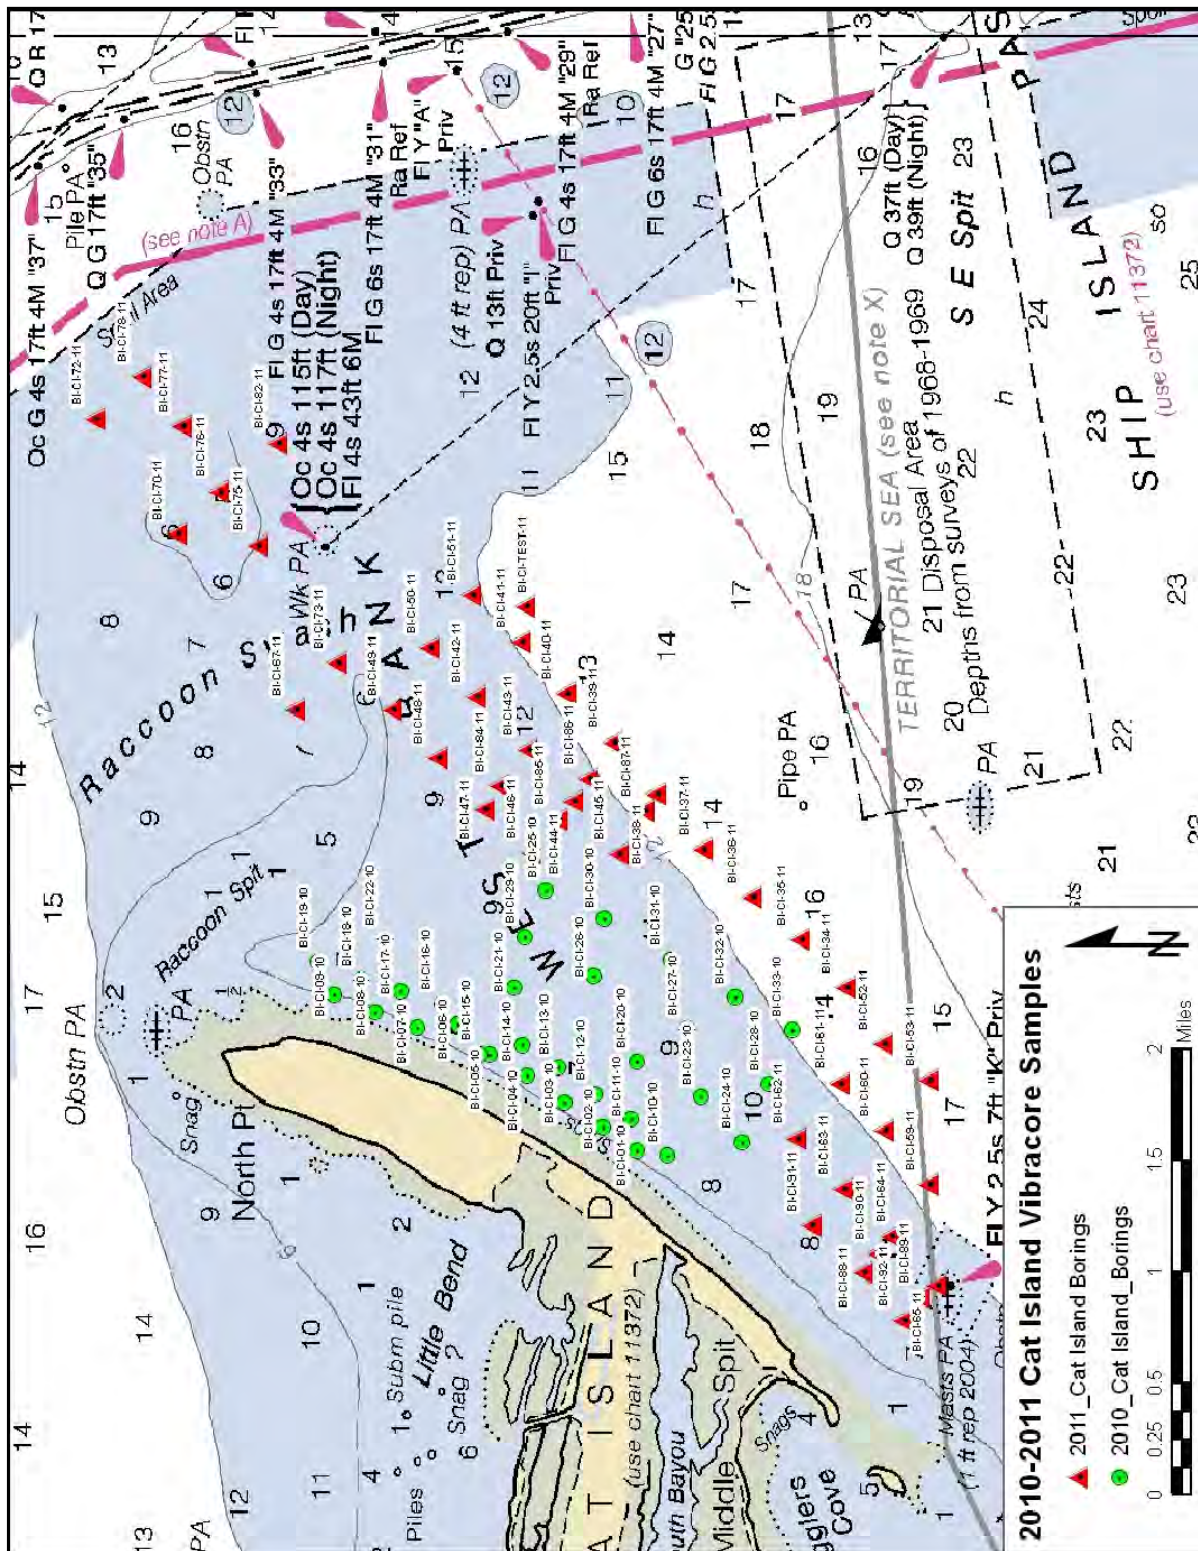

Figure 5.2.1.1 – 2010 Vibracores completed for Gulfport Channel sampling area.

### 5.2.2 CAT ISLAND INVESTIGATION AREA

Potential borrow sites were investigated offshore of the eastern beach at Cat Island. The USGS's geophysical surveys in 2010 indicated that extensive sand deposits were available in this area. The Cat Island shoal and the Ship Island Pass shoal were identified and estimated to contain 25 million cubic meters and 7 million cubic meters of sediment, respectively, with over 90% estimated to be sand (Flocks and others, 2011). Initially, thirty-three (33) vibracores were completed during the 2010 sampling event and confirmed the presence of the sand. These vibracores were mostly near shore, however. An additional forty-five (45) vibracores were completed during the 2011 sampling event to expand the investigation into deeper water. The 2011 sampling event was implemented after 3D modeling on all potential borrow sites showed adverse wave effects would occur if desired cut depths were used during dredging of the 2010 core sites. Although extensive sand deposits were identified, the recommended area will have an average cut depth of approximately five (5) feet to minimize effects of wave refraction over the site after excavation. Based on the 2011 vibracores, approximately 2.1 million cubic yards of sand were delineated from an area of approximately 282 acres, for dredging and placement on the beach at Cat Island. The area-weighted, average D50 grain size is 0.20 mm and the predominant color is light gray (with a Munsell Value of 6) for these samples. The vibracores indicate that the seafloor surface is predominantly poorly graded, fine-grained sand-sized quartz, with some siltier sand in the northern half of the area. Grain size grades finer with depth so dredging should be done in such a way as to produce a thicker cut to achieve the coarsest mix of the sediments. This area is also within the designated threatened species habitat for the Gulf Sturgeon. However, the volume of material to be removed will be relatively low and, due to the widespread availability of the sand in this area, a very shallow borrow excavation can help minimize disruption of the habitat. The general layout of the vibracores completed for the investigation for borrow material for Cat Island is shown in Figure 5.2.2.1. The table in Appendix C provides the coordinates of the vibracores, the Unified Soil Classification System designation of the samples, the Munsell Color designations for wet and dry samples, and grain size data from the laboratory gradation analyses. Drilling logs and full lab gradation data are included in Appendix C.

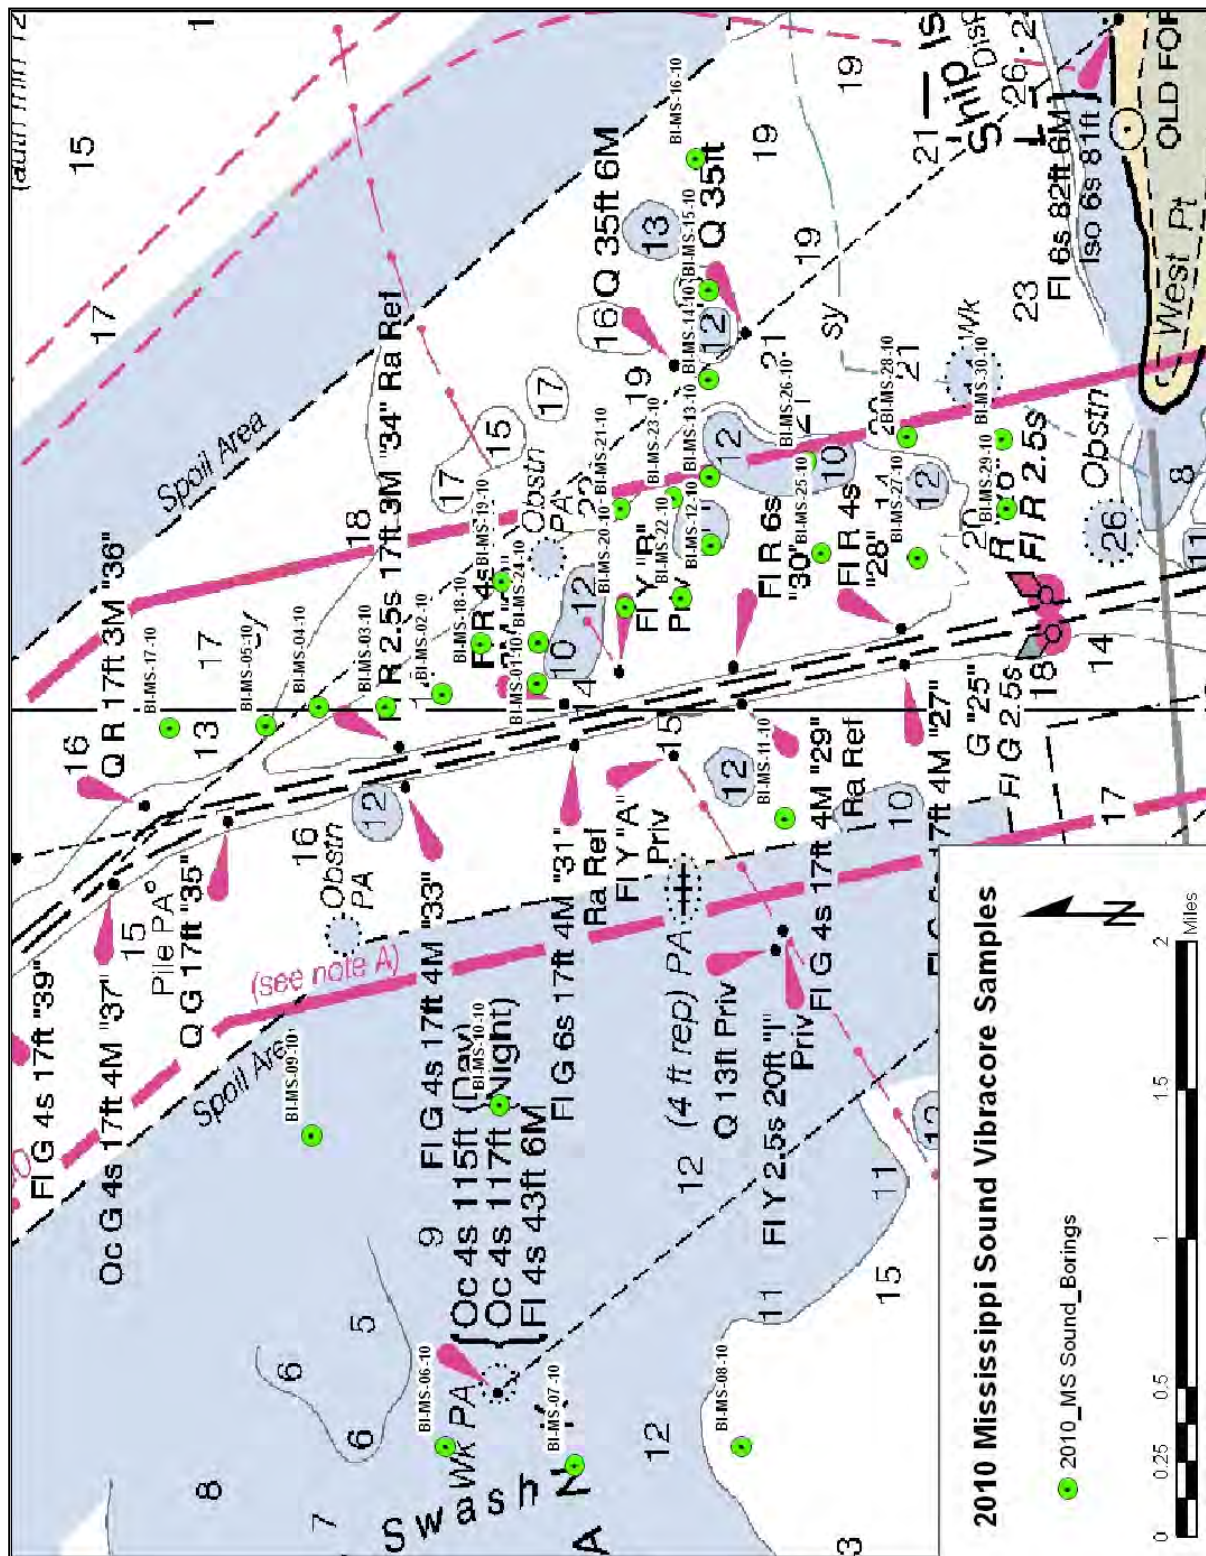

**Figure 5.2.2.1 – 2010 (green circles) and 2011 vibracores (red triangles) completed for the investigation for borrow material at Cat Island.**

**5.2.3 MISSISSIPPI SOUND INVESTIGATION AREA**

Previous investigations have revealed that some areas in Mississippi Sound, near West Ship Island, have large sand deposits at the surface suitable for beach re-nourishment (Oivanki, 1995). This same localized area was described by Otvos (1975/76) as sandy, while most of the surface sediments in this area of the Sound are described as muddy. A previous geotechnical investigation by the USACE also confirmed the presence of this sand deposit. The boundaries of the sand deposit were defined by the USGS's geophysical investigation and a series of sixteen (16) vibracores were completed in 2010 to validate the geophysical data. An additional fourteen (14) 2010 vibracores were completed to further delineate the deposit. Unfortunately, the sand from this area is finer-grained than desired for these projects. Also, it is located in a designated threatened species habitat for the Gulf Sturgeon. While this information would not preclude the use of this material, it would make it less desirable for potential borrow sites. The layout of the vibracores completed for Mississippi Sound is shown in Figure 5.2.3.1. The table in Appendix D provides the coordinates of the vibracores, the Unified Soil Classification System designation of the sample, the Munsell Color designations for wet and dry samples, and data from the laboratory gradation analyses. Drilling logs and full lab gradation information are included in Appendix D.

**Figure 5.2.3.1 - Layout of the 2010 vibracores completed for the Mississippi Sound area.**

#### 5.2.4 SHIP ISLAND PASS INVESTIGATION AREA

The 2010 USGS geophysical survey included the area located between the western edge of the Gulfport Navigation Channel and Cat Island. The survey was expected to locate a very large deposit of sand associated with an ebb tidal delta just south of the western tip of West Ship Island. However, the vibracores did not support this expectation. Potential sand deposit locations on the northern portion of the pass were consistent with the area identified by Otvos (1975/76). The geophysical surveys also confirmed the presence of shoals in this area (Twichell et al., 2011). Ten (10) 2010 vibracores were completed to define and confirm the extent of the deposit. Unfortunately, the grain size was finer than desired for placement. The unweighted D50 for this study area was 0.16 mm. Also, like other sand deposits north of the islands, the area is within the designated threatened species habitat for the Gulf Sturgeon. The disposal site adjacent to the channel, south of Ship Island, was also sampled. The vibracores contained only thick clay, with a thin veneer of sand on the northern edge of the site. The material located adjacent to the western tip of West Ship Island (Ship Island Pass borrow area in Table 6.1) was approved for placement on the northern shore of West Ship Island by the NPS because it is composed mostly of material migrating westward from the island. The old Gulfport Channel acts as a sink and fills up as the natural longshore transport of the island's sediment moves westward. This material had been used in previous NPS beach nourishment projects on the island. No vibracores were taken in this sand body, however. Instead, a proxy sample was taken from the north side of West Ship Island. The material consists of poorly graded, medium- to fine-grained, sand-sized quartz with an unweighted D50 of 0.48 mm, with percent fines being less than 5%. Dry Munsell value is 6. This borrow area is estimated at approximately 20.8 acres in size with approximately 480,000 cy of material available. Figure 6.2 shows the approximate outline of the borrow area. The layout of the vibracores completed for Ship Island Pass is shown in Figure 5.2.4.1. The table in Appendix E provides the coordinates of the vibracores, the Unified Soil Classification System designation of the sample, the Munsell Color designations for both wet and dry samples, and the laboratory gradation analyses data. Drilling logs and full gradation information are included in Appendix E.

**5.2.5 SHIP ISLAND INVESTIGATION AREA**

At the completion of the geophysical surveys and the initial field interpretations, one of the primary targets identified was an area south of Camille Cut and East Ship Island identified as Loggerhead Shoal and tidal delta (Figure 4.1.2.3). Using the survey data, the USGS identified eleven (11) locations for 2010 vibracores. These vibracores indicated a large expanse of quality sand. Therefore, fifty-four (54) additional 2010 vibracores were completed to fully define the sand deposit. Initial analysis of the vibracore data indicated that approximately twenty-two (22) million cubic yards of fine-grained sand was available from two locations within that general area. This area was selected for further analyses by computer modeling to predict any adverse effects from wave refraction caused by use of the area as a borrow site because the seafloor has such a gradual slope. Wave and hydrodynamic modeling indicated that the footprint of the borrow area needed to be altered to reduce potential wave impacts on the fill placed in Camille Cut. As borrow area design progressed and modeling showed a need to reduce and reshape the borrow area, the new borrow area was whittled down to 1.2 mcy with an average D50 grain size of 0.21 mm, a dry Munsell color of light gray, and a dry Munsell value of 7. The D50 grain size of the sand is smaller than desired for a potential borrow source. The vibracores indicated that grain size grades finer with depth, so dredge cuts should be thicker to more fully composite the sediments. Potential solutions to make this borrow site more suitable could include applying overfill to mitigate erosion losses or mixing with sand from other borrow sites to increase the average D50. The layout of completed vibracores is shown in Figure 5.2.5.1. The table in Appendix F provides the coordinates of the vibracores, the Unified Soil Classification System designation of the samples, the Munsell Color designations for wet and dry samples, and data from the laboratory gradation analyses. Drilling logs and full lab gradation information is included in Appendix F.

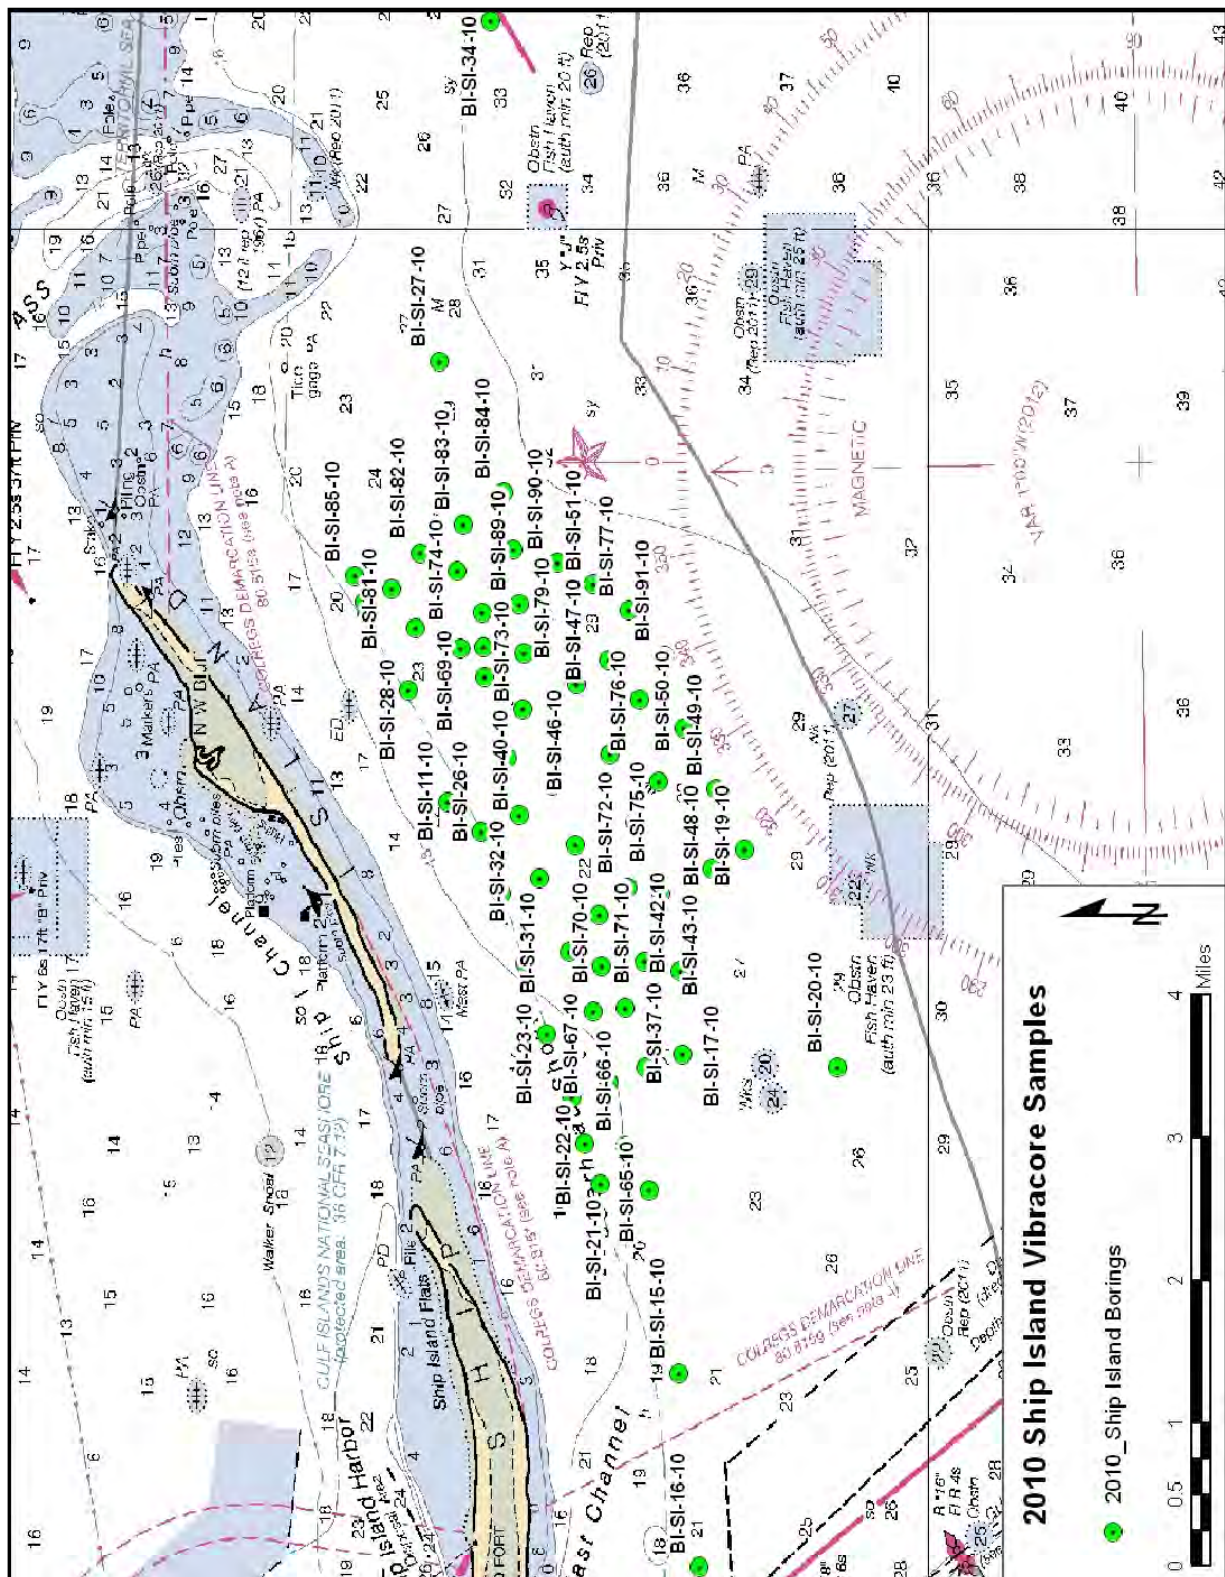

Figure 5.2.5.1 – General layout of the Ship Island vibracores completed for the investigation.

### 5.2.6 DOG KEYS PASS INVESTIGATION AREA

Two separate, well-defined ebb tidal deltas located east of East Ship Island and to the west of Horn Island are associated with Little Dog Keys Pass and Dog Keys Pass (Figure 4.1.2.3). Initially, the deltas were believed to contain large volumes of high quality sand, but the exact conditions of littoral sediment transport relationships were not well defined. This area was added for further investigation in an updated sediment budget to determine if sediment transport was terminating southward and extending these deltas. The geophysical survey provided updated bathymetry and information on the extent of the deposits. The survey also indicated buried lowstand channels south of the tidal deposits. The USGS located twelve (12) Phase One vibracores to validate their geophysical data. An additional twelve (12) 2010 vibracores were added to further define the limits of the sand deposit, for a total of twenty-four (24) vibracores in 2010. The vibracores in the north indicated that the sand on the delta is fairly clean SP, but too fine for the project. Only one vibracore on the delta had an acceptable grain size. Vibracores off the delta indicate that the typical sediments for the area are clays and silts which are not useful for the project. Aside from the grain size issue, this area appears to be within the active littoral system and would not be considered for borrow. South of the deltas, vibracores targeting the buried lowstand channels had thick clay overburden atop fine grain sand, which is finer than desired for this project. Therefore, it will not be considered for use as borrow. The layout of the vibracores for Dog Keys Pass is shown in Figure 5.2.6.1. The table in Appendix G provides the coordinates of the vibracores taken in the area, the Unified Soil Classification System designation of the sample, the Munsell Color designations for wet and dry samples, and select data from the laboratory gradation analyses. Drilling logs and full gradation information are included in Appendix G.

Figure 5.2.6.1 - General layout of the vibracores completed for the Dog Keys Pass area.

**5.2.7 HORN ISLAND PASS INVESTIGATION AREA**

Horn Island Pass is located between Petit Bois Island to the east and Horn Island to the west. Disposal Area 10, a USACE disposal area, is located in the pass between the two islands. It contains a man-made island, locally known as Sand Island. The pass also has a shipping channel (Pascagoula Bar Channel) to the east and two pipelines that run north-south through the western half of the area. The USGS geophysical survey identified a tidal deposit at the southern entrance to the pass. However, Horn Island Pass was not selected initially as an area to investigate for borrow sites because of the distance to potential placements and indications that all potential sand deposits would be in the active littoral zone. Ambient water depths in this area range from 19 to 40 feet. During the study of the sediment budget for the barrier islands, it was noted that several mounds of sediment just south of Horn Island Pass had the potential for sand resources. These mounds were created by the disposal of dredged material from the bar channel section of the Pass where much of this material was sand naturally transported from Petit Bois Pass-OCS Island and deposited in the channel.

Twenty-six (26) vibracores were completed for the 2010 sampling event, focusing on the main disposal mound to the east. The recovered cores illustrated that the mounds contain suitable sand for use in the MsCIP Barrier Island project. Because the sediment mounds are man-made, they contain discontinuous sandy layers atop the in-situ seafloor comprised mostly of sandy silts and clays. As a result, the mound's sandy veneer pinches off at the lateral margins of the mounds. This makes it difficult to design a borrow area that can be efficiently dredged near the margins without dredging up the poor sediments, or skipping large swaths because the deposits are too thin. Therefore, this area was not considered for a potential borrow area after the 2010 sampling event. However, with the potential need for additional sand, it was decided to investigate the area further. Additional vibracores were needed to determine the sand content and structure of the mounds to the west, adjacent to the pipelines, and further to the north of the 2010 vibracores. For the 2012 sampling event, fifteen (15) vibracores targeted the three major dredged sediment mounds in the area and the tip of the ebb-tidal shoal. The results correlated with the 2010 vibracores. That is, the other mounds also contain suitable sand in varying thicknesses deposited atop unsuitable in-situ material. Twenty-two (22) vibracores were also taken adjacent to the Pascagoula Bar Channel margins to determine if this material would be suitable for use. None of these vibracores

indicated the material would be suitable for use with this project because they are mostly clays, silts, and silty sands. Three borrow areas were delineated based on the combined results of the 2010 and 2012 sampling events. In 2013, USACE conducted another sampling event, with eleven (11) vibracores taken south of the 2012 samples on the dredge disposal mounds. The intent of these vibracores was to further expand the borrow area delineated following the 2012 sampling event.

Only the mounded areas are suitable for borrow material for this project. In general, vibracores that intersected the tops of the mounds recovered poorly graded, medium- to fine-grained, sand-sized quartz (SP) with very little fines and trace shell fragments throughout. Sand thicknesses on the mounds ranged from one foot to 11.8 ft, with an average thickness of 6.1 ft. D50 grain size for samples in the mounds ranged from 0.15 mm to 0.34 mm, with an average D50 of 0.28 mm. Percent fines ranged from 1.6% to 14.3%, with an average of 4.9%. Typical dry Munsell Color Value was 7, with a Munsell Color of Light Gray. Overburden was virtually non-existent on the tops of the mounds. Below the initial top sand layer, the sediments quickly grade to silty and clayey sands (SM and SC), usually underlain by intermittent layers of clay (CL and CH) and silt (ML and MH). Dry Munsell Color Value typically decreases with increasing depth. D50 grain size also typically decreases with depth. Dredge cut elevations should leave a buffer between the sand and the poorer sediments because the transition between the two occurs rapidly. In general, the sand deposits do grade finer with depth and dredge cuts should attempt to mine the full thickness with each pass to maximize mixing of the sands to create the largest composite grain size.

Vibracores paralleling the Pascagoula Bar Channel contained unsuitable sand for this project. The vibracores generally contained significant volumes of silt and clay in the northern half of the group, but did have a veneer of silty sand in the southern half of the group. For the vibracores in the south, the grain size of the sand is too small for use in this project. D50 ranges from 0.15 to 0.20 mm, with an average D50 of 0.17 mm. Percent fines ranges from 0.4% to 19.8%, with an average of 15.1%. Munsell Color Value ranges from 5 to 6, with an average of 5.05. Typical Munsell Color is Olive Gray. Based on this information, the areas paralleling the channel are not considered suitable for this project.

The layout of the 2010-2013 vibracores is shown in Figure 5.2.7.1. The table in Appendix I provides the coordinates of the vibracores, the Unified Soil Classification

System designation of the samples, the Munsell Color designations for wet and dry samples, and data from the laboratory gradation analyses. Drilling logs and full lab gradation information is included in Appendix I.

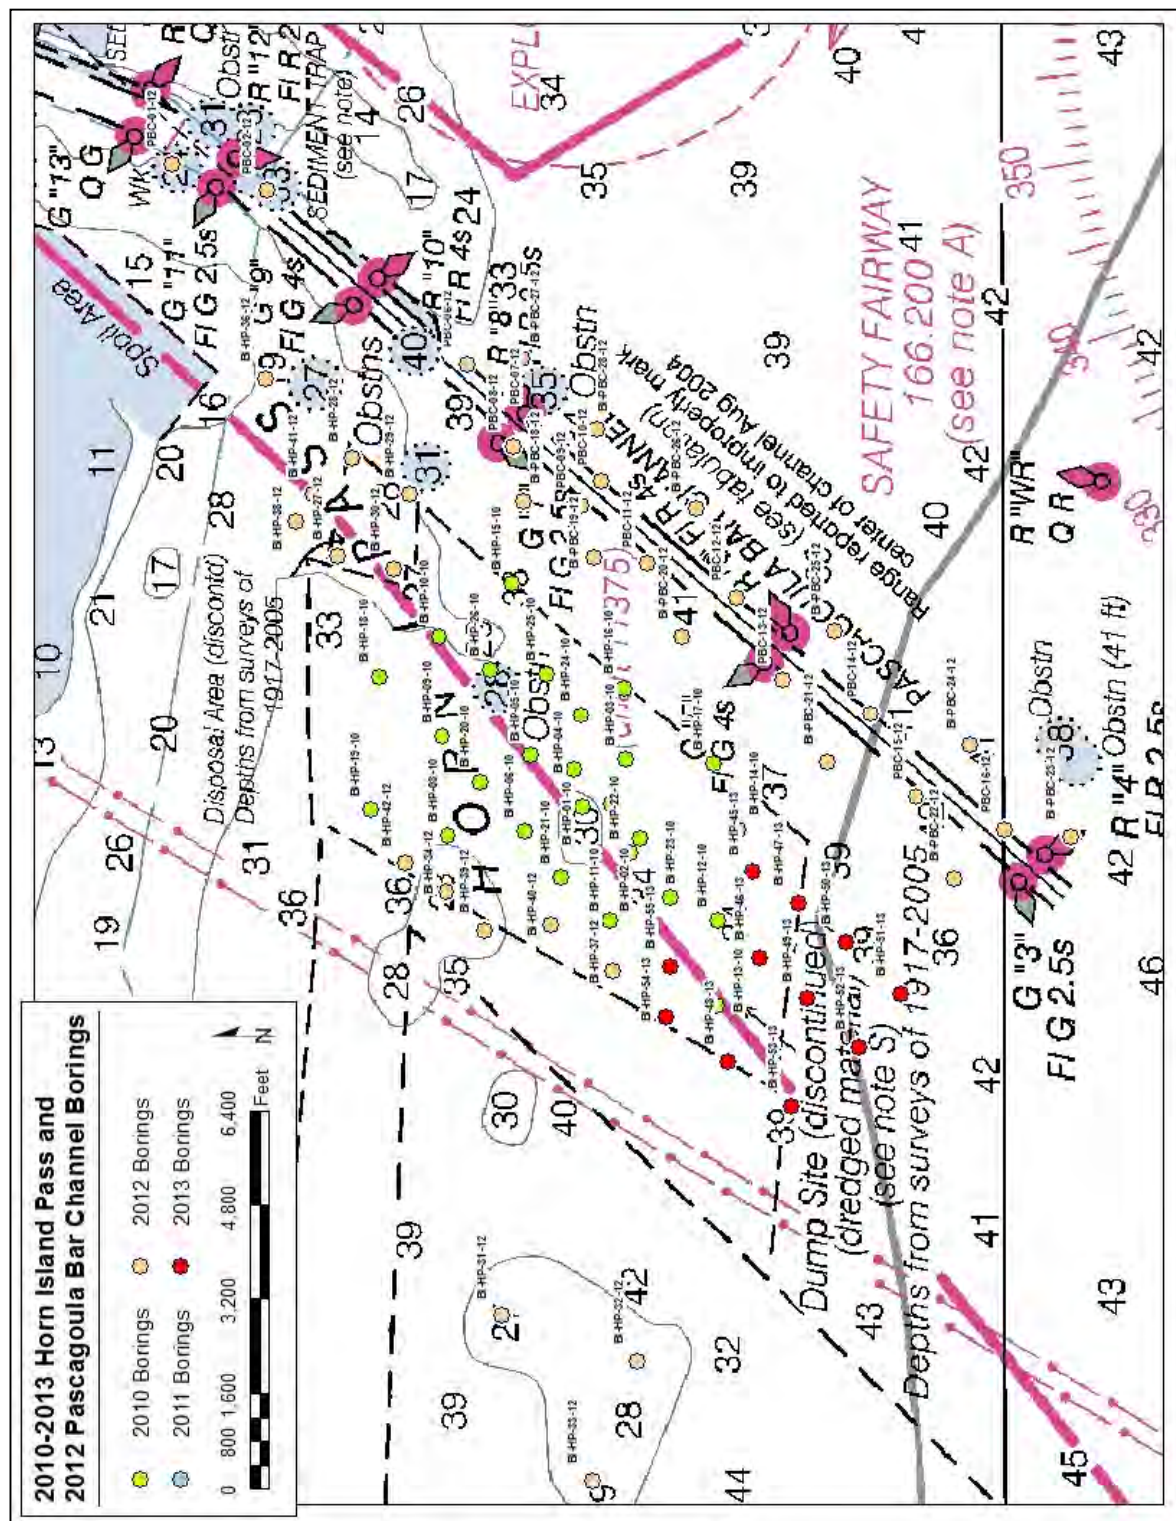

Figure 5.2.7.1 - General layout of the vibracores completed for the investigation of borrow material from Horn Island Pass area.

**5.2.8 DISPOSAL AREA 10 (DA-10) INVESTIGATION AREA**

Disposal Area 10 (DA-10) is a man-made island created from dredged material from the Pascagoula Bar Channel. It is located in Horn Island Pass, less than one mile northwest of the western tip of Petit Bois Island, MS. Sand placement in this area was initially intended to provide sediment to the littoral system. However, the sediment budget study (Byrnes) for the barrier islands has shown that its northern position in the pass prevents it from contributing any significant sediment quantities to the littoral system, resulting in little to no erosion of the deposited material over time and hence the accidental creation of a relatively stable island. Although not originally considered a viable option prior to the 2010 sampling event due to its location within the littoral system, DA-10 was added to the list of potential investigation sites for the 2011 sampling event following the completion of the sediment budget study by Byrnes. Hydrologic modeling of this area showed borrowing material would have minimal effects on wave action in the area.

DA-10 has good potential for a borrow source because of its location, material quality, and its minimal effect on wave action in the area. It would also take sand that is not actively moving in the littoral system and transport it downdrift. The area-weighted average D50 grain size is 0.32 mm and dry Munsell color is predominantly light gray with an average dry Munsell value of 7. There are approximately 5.1 million cubic yards available. The initial borrow area design called for 5.1 mcy of material to be removed. However, the presence of a wetland on the island prompted a new design to minimize the impacts to this area. The second design reduced the quantity of sand to be removed to 3.7 mcy. In 2013, the decision was made to not use DA-10 because NPS regulations regarding borrow areas within park boundaries would not allow this material to be used.

The layout of the vibracores completed for the investigation is shown in Figure 5.2.8.1. The table in Appendix H provides the coordinates of the vibracores, the Unified Soil Classification System designation of the sample, the Munsell Color designations for wet and dry samples, and data from the laboratory gradation analyses. Drilling logs and full lab gradation information are included in Appendix H.

Figure 5.2.8.1 - Layout of the vibracores completed for the 2011 investigation for borrow material from Disposal Area 10.

**5.2.9 PETIT BOIS PASS- ALABAMA INVESTIGATION AREA**

Petit Bois Pass extends from Petit Bois Island, MS, eastward to Dauphin Island, AL. There is a natural gas pipeline running north-south through the eastern portion, and two pipelines running north-south through the western portion. The initial field interpretations of the 2010 USGS geophysical survey indicated that large deposits of sand were present south of the pass, mostly in the eastern portions in the form of shoals and infilled lowstand channels. Their initial volume estimate for these shoals was 56 million cubic meters of sediment, with >90% sand content (Twichell, 2011). These shoals are independent of the littoral processes affecting the movements of Petit Bois Island and the west end of Dauphin Island, and have remained relatively stable over the course of the last century. These shoals generally taper at the ends, with slope angles at the seaward tips up to 1.4° and flattening out with decreasing water depth. They do not appear to have a steeper shoreward or seaward side, interpreted as meaning they are not actively moving (Twichell, 2011). During the 2010 sampling event, seventeen (17) initial vibracores were completed and located very high quality sand in some areas. Then, an additional eighty-nine (89) vibracores were completed to fully outline the deposit. During the 2011 sampling event, seventeen (17) additional vibracores were completed to further delineate the sand deposits. Two potential borrow areas were identified. Petit Bois Pass-Alabama West borrow area is located approximately 3 miles east-southeast from the eastern tip of Petit Bois Island, MS, and 2.8 miles southwest from the western tip of Dauphin Island, AL. Petit Bois Pass- Alabama East borrow area is located approximately 2 miles south of the western tip of Dauphin Island.

A north/south-running natural gas pipeline bisected the Petit Bois Pass- Alabama West borrow area. The pipeline owners voiced concern about the possibility of damage to their pipeline in the future caused by the removal of borrow material on either side of it. Modeling was conducted by an independent third-party contractor, in conjunction with the pipeline company, to determine the long term effects of the borrow area excavations on the pipeline. The results of this modeling showed that given a proper buffer around the pipeline, the proposed borrow areas would have negligible effects on the pipeline. The borrow quantity for Petit Bois Pass- Alabama West was recomputed, with a one thousand-foot buffer added around the pipeline, to determine the loss of sand in the footprint of the pipeline. The pipeline and buffer footprint effectively prevents the removal of over one million cubic yards of material from the Petit Bois Pass- Alabama West borrow area.

Therefore, during the 2012 sampling event, seventy-eight (78) vibracores were taken around the perimeter of the existing borrow areas. The intent of the sampling was to determine if it was possible to expand the existing borrow area perimeters and maximize each area's potential yields in an attempt to recoup the losses due to the pipeline buffers.

Based on the vibracores from the 2010-2012 sampling events, the sand quality is very good in these areas (D50: ~0.32 mm, % Fines: <5%, Munsell Color Value: 6) with minimal to no overburden, particularly on the shoals. The Petit Bois Pass-Alabama East and West borrow areas were reconfigured to incorporate the new data from the 2012 vibracores and accommodate the pipeline buffer. The pipeline now serves as the arbitrary dividing line between the east and west sampling areas.

For Petit Bois Pass- Alabama West, the sand deposit is exposed within the perimeter of the proposed borrow area. The 2012 vibracores along the northern boundary contained suitable sand, but with some sand having a darker Munsell Value than desired. However, the ambient water depth ranges from 18 to 28 feet in this area which might be considered too close to the active littoral zone for significant expansion into this area (Figures 5.2.9.1 and 5.2.9.2). The sand body begins to be overlapped by clays and silts just south of the southern boundary and thick clay beds cover the majority of the area. Vibracores with suitable sand south of this borrow area appear to be on shoals only. Expansion to the west is limited by the pipeline and buried cable. Expansion to the east is limited by the natural gas pipeline.

Samples from suitable vibracores had a D50 range of 0.18 to 0.39 mm, with a weighted mean D50 of 0.30 mm. Percent fines ranged from 0.8% to 7.7%, with an average of 2.7%. Dry Munsell Color Value ranged from 4 to 8, with an average of 6. Typical dry Munsell Colors were White 2.5Y 8/1 (21%), Light Brownish Gray 2.5Y 6/2 (20%), and Light Gray 2.5Y 7/2 (17%). Overall, white and light gray were the two predominant colors at 25% and 29%, respectively.

For Petit Bois Pass- Alabama East, the sand deposit is exposed within the perimeter of the proposed borrow area, similar to Petit Bois Pass- Alabama West. The vibracores indicate that the sand body becomes overlapped by clays in the northeast, indicating the sand body is either buried deeper than is feasible for use or it terminates beneath the clay. In either case, further expansion of the borrow area in

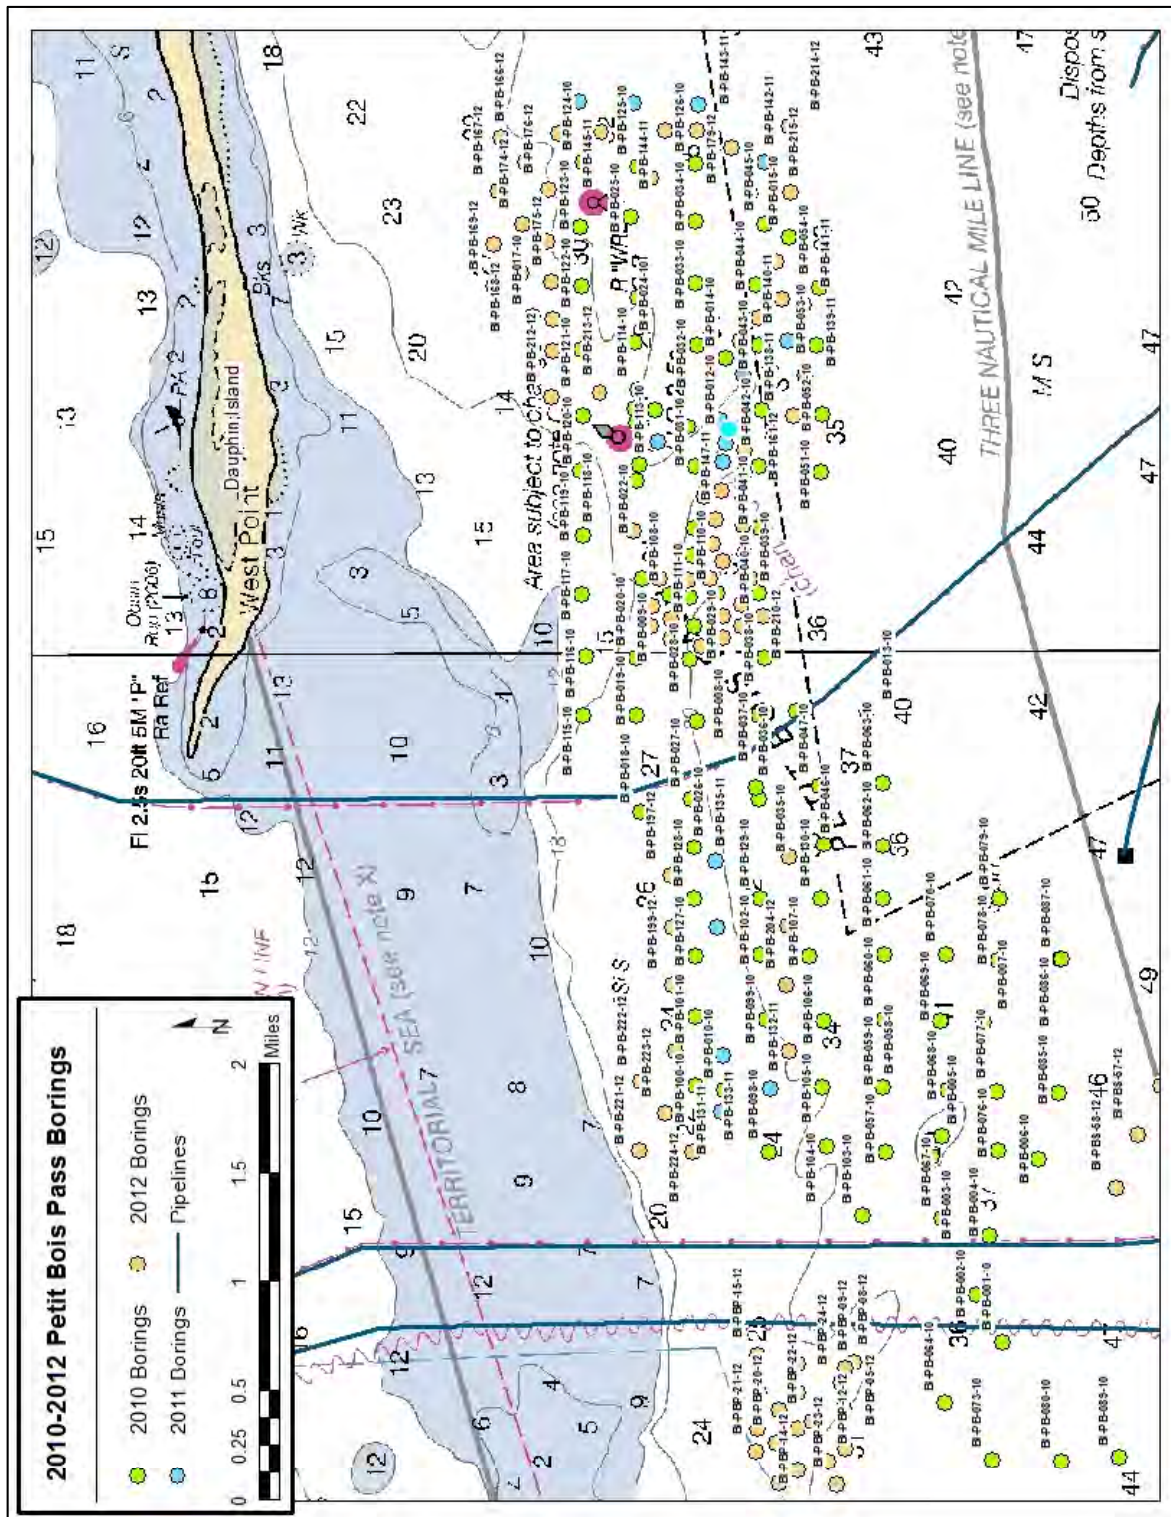

this direction is limited. Along the northwestern portion of the northern boundary, vibracores contained suitable sand. However, shallower water depths may prevent expansion in this direction. The eastern vibracores indicate that limited expansion is possible in this direction, because the sand begins to be overlapped by silts and clays further east. The vibracores in the southwest indicate the sand body beginning to be overlapped by clays and silts before being completely covered or terminating. The south central vibracores indicate that the sand body begins to become covered by overburden on the southwest and southeast sides of a shoal extending south. The surficial sand begins thinning out as well on the southeastern side of this shoal. Vibracores from the southeastern corner of the borrow area indicate that the borrow area can be expanded along the shoal which extends from this corner. Vibracores did not delineate the farthest extent of the sand in this direction. There are several shoals running northwest/southeast through the southern half of the sampling area that do contain sand. But, they appear to have thinner veneers of sand than desired. Also, the troughs between the shoals appear to have significant clay layers, making the dredging of this area difficult.

Samples from suitable vibracores had a D50 range of 0.21 to 0.45 mm, with a weighted mean D50 of 0.32 mm. Percent fines ranged from 0.5% to 17.8%, with an average of 4.1%. Dry Munsell Color Value ranged from 5 to 8.5, with an average of 6.8. Typical dry Munsell Colors were White 5Y 8/1 (16%), Light Gray 2.5Y 7/2 (13.2%), and Light Brownish Gray 2.5Y 6/2 (10%). Overall, light gray and white were the two predominant colors at 33% and 24%, respectively. The vibracores in the east that are “Borderline” for color have adequate grain size and are slightly silty. It is expected that if the sand in this area is used, many of the fines would wash out during dredging and placement, thereby lightening the overall color of the sand.

Vibracores from both borrow areas indicate that the grain size of the sand does grade slightly finer with depth. However, they also indicate that dredging should be able to occur in longer, shallower runs without having an issue with inadequate mixing of grain sizes prior to placement because the finer sediments are generally still within established tolerances.

A layout of the vibracores is shown in Figures 5.2.9.1, 5.2.9.2, and 5.2.9.3. The table in Appendix L provides the coordinates of the vibracores, the Unified Soil Classification System designation of the sample, the Munsell Color designations for

wet and dry samples, and data from the laboratory gradation analyses. Drilling logs and full lab gradation information is included in Appendix L.

**Figure 5.2.9.1 - Layout of the vibracores completed for the 2010-2012 investigation for borrow material from the Petit Bois Pass- Alabama area.**

**Figure 5.2.9.3 – 2010-2012 Vibracores completed for the Petit Bois Pass-Alabama East area.**

**5.2.10 PETIT BOIS PASS-MISSISSIPPI INVESTIGATION AREA**

Petit Bois Pass- Mississippi is a sampling area located approximately 1.3 miles southeast of Petit Bois Island, in Mississippi state waters. A major shoal feature was identified in this area using bathymetry. It is approximately 2.8 miles long and runs northwest to southeast near the intersection of the NPS's Gulf Islands National Seashore boundary and a buried cable (shown on the map as a pipeline) running through Petit Bois Pass (Figure 5.2.10.1). The shoal is in ambient water depths ranging from 25 ft to 37 ft. Due to its proximity to the Pass, it was speculated that this shoal might have similar sediment characteristics to the sand found in the Petit Bois Pass- Alabama East and West borrow areas. The USGS used its geophysical survey data from the 2010 survey to assist in locating vibracores along its crest and delineate the shoal's lateral extents. Other vibracores were situated along the shoal margins to gain a better understanding of the shoal's structure and the surrounding sediments. Figure 5.2.10.1 shows the location of the sampling area and the vibracores taken there.

Sampling results indicate that the shoal crest has thick deposits of suitable sand in the northwest portion of the shoal, closer to Petit Bois Island. In general, vibracores that intersected the top of the shoal recovered poorly graded, medium- to fine-grained, sand-sized quartz (SP) with very little fines (< 5%) and trace shell fragments throughout. Cleaner sand (SP, SP-SM) thicknesses in the vibracores ranged from 2 feet to 15.2 feet, with an average thickness of 8.7 feet. Below the poorly graded sand (SP) layers, the sediments quickly grade to silty and clayey sands (SM and SC), usually underlain by intermittent layers of clay (CL/CH) and/or silt (ML/MH). Munsell Color Value typically decreases with increasing depth. D50 grain size also typically decreases with depth. Off the shoal, sand is typically only surficial, one to two feet thick, and is underlain by clays and silts. Overburden was virtually non-existent on the top of the shoal. Figure 5.2.10.2 is a Triangulated Irregular Network (TIN) map created in ArcMap using the sand thicknesses observed in the vibracores to create the isolines. It shows that the sand thins out abruptly further away from the crest of the shoal coinciding with the changing bathymetry. The USGS' geophysical data for this area also confirms that the sand thins out off the shoal. Borrow area design needs to focus on maximizing the cut into the crest of the shoal. The sand deposit is thickest and cleanest in this area, allowing for deeper dredge cuts. The southeast end of the shoal can also be mined.

The samples had a typical dry Munsell Color Value of 7 (58% of sample volume). Of the samples with suitable sand, the majority of sample volume (49% of sample volume) had a Munsell Color of 5Y 7/2 (LT Gray). 5Y 6/2 (LT Olive Gray) was the second most abundant color by volume. However, the percentage of light gray to white color was 71% for the entire sample volume. D50 grain size for samples in the shoal ranged from 0.13 mm to 0.48 mm, with a weighted mean D50 of 0.31 mm. Sand thicknesses within vibracores on the shoal ranged from 2 to 15.2 feet, with an average thickness of 8.7 feet. In several vibracores (BI-PBP-2-12, BI-PBP-6-12, BI-PBP-20-12, BI-PBP-21-12) the vibracore sampler could not penetrate the dense sand, making it difficult to assess the true thickness of the sand body from the vibracores. The penetrometer graphs in Appendix J attest to the difficulty the vibracorer had in penetrating these areas. There is also a slightly thicker mound on the southeast tip of the shoal with suitable sand, but then the sand thins out rather quickly moving away from the crest of the shoal to the northeast, east, south, and west. (Figure 5.2.10.2)

The more continuous nature of this shoal makes borrow area design and dredging less difficult than Horn Island Pass or Petit Bois Pass-OCS. Borrow areas should be constrained to the shoal to optimize sand recovery, while any dredging off the shoal will likely result in recovery of mostly poor material (SM, SC, CL, ML). The east side of the shoal, near vibracores BI-PBP-18-12, BI-PBP-13-12 and BI-PBP-06-12 should be dredged with cuts designed to maximize mixing of sediments. Other than the east side of the shoal, the grain size of the vibracores indicates that shallower cuts parallel with the long axis of the shoal would be acceptable to maintain the grain size of the placed material. The table in Appendix J contains a consolidated list of the vibracores and their respective samples. It includes select laboratory gradation data, the USCS classification, and the Munsell color classifications. Drilling logs and lab data are included in Appendix J.

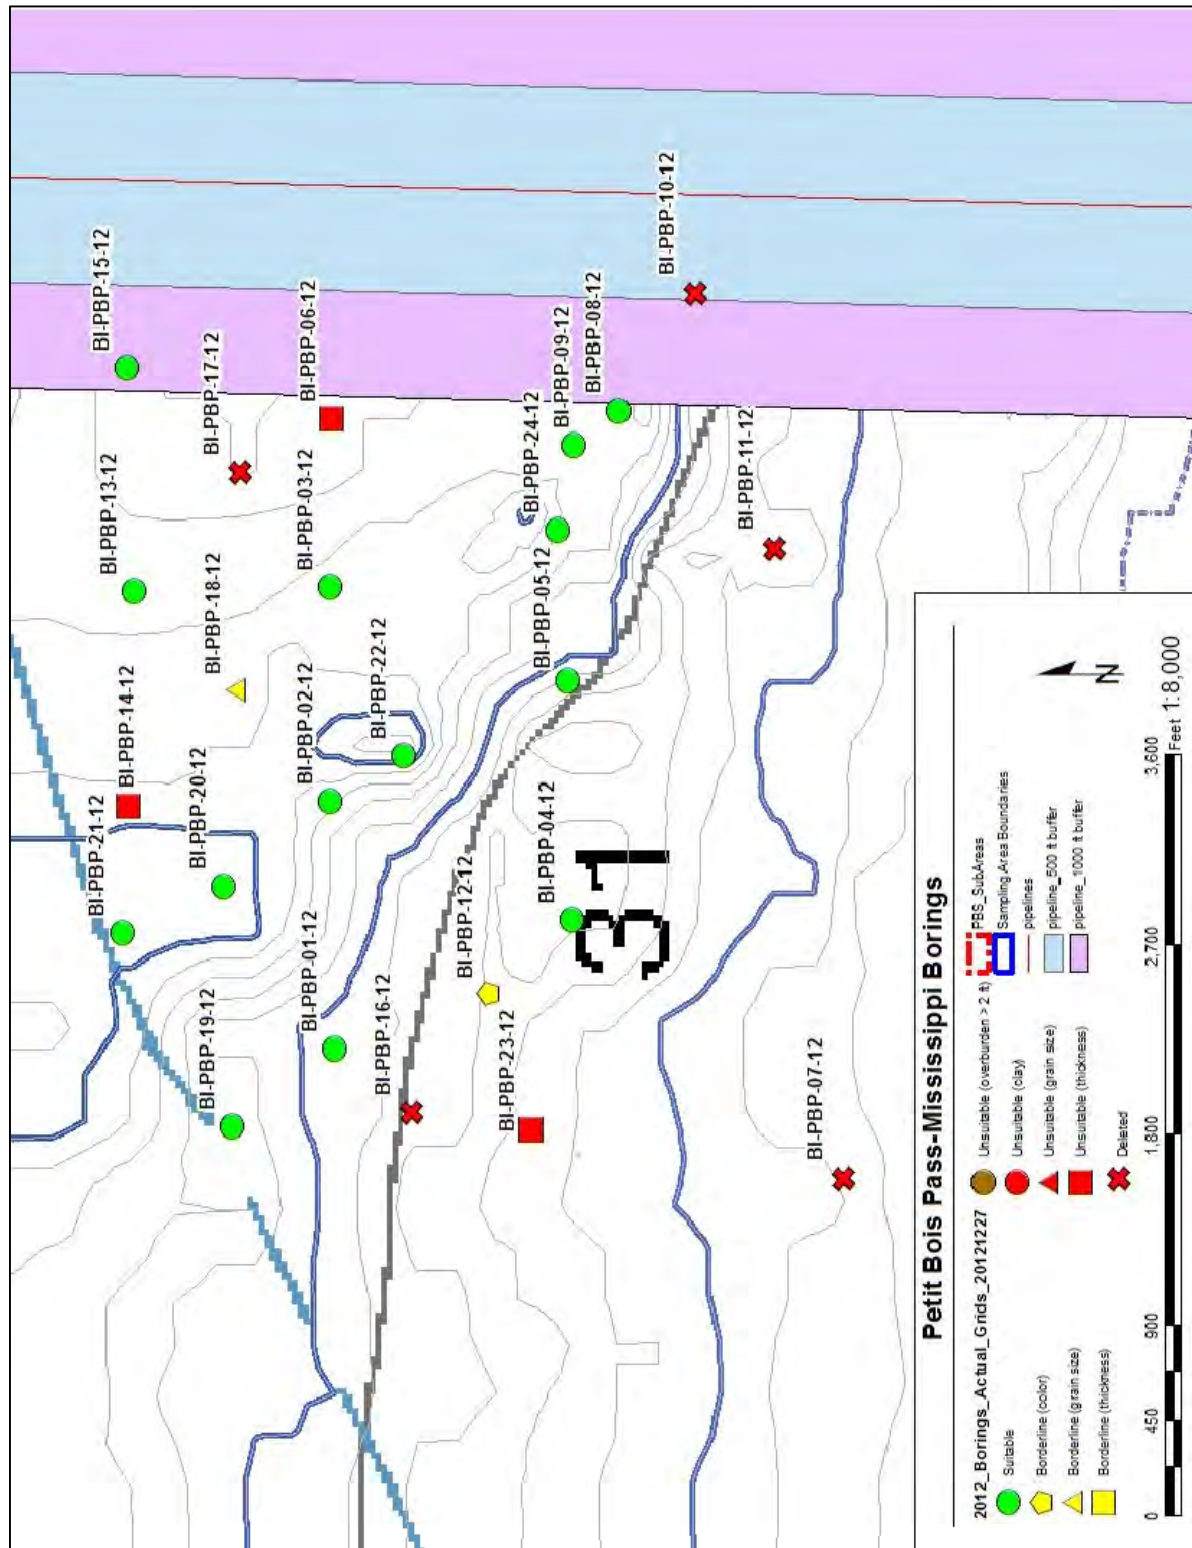

Figure 5.2.10.1 2012 Vibracores for Petit Bois Pass- Mississippi sampling area with bathymetric contours illustrating the main shoal in the area. The blue contours are at 5-ft intervals.

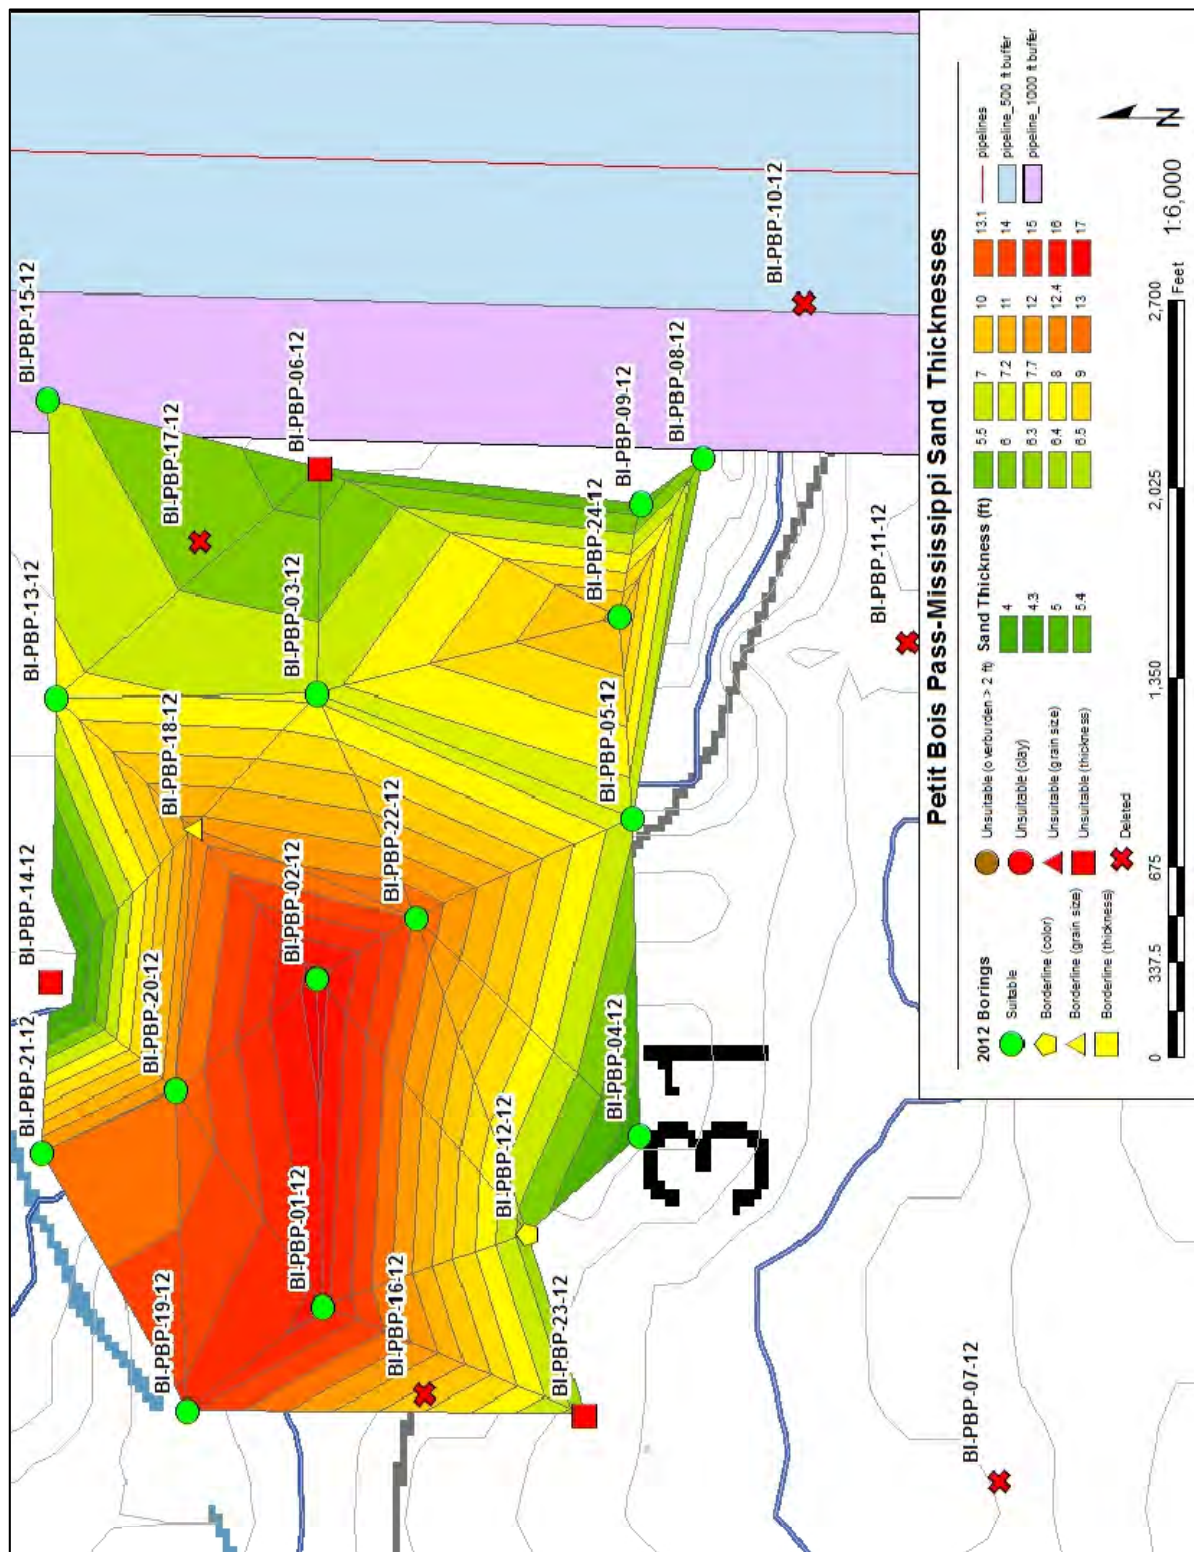

Figure 5.2.10.2 Map of sand thicknesses in the Petit Bois Pass- Mississippi sampling area.

**5.2.11 PETIT BOIS PASS- OUTER CONTINENTAL SHELF (OCS)  
INVESTIGATION AREA**

The Petit Bois Pass-Outer Continental Shelf (OCS) sampling area is located approximately 3 to 6 miles south of Petit Bois Island and Petit Bois Pass. It is divided by a pipeline and buried cable running north-south through the center of the area, and is bounded in the south by pipelines running east-west. The western area (PBP-OCS West) overlaps Mississippi and federal waters, while the eastern area (PBP-OCS East) is almost entirely in federal waters. Ambient water depths in these areas range from 40 to 68 feet (Figure 5.2.11.1). There are several shoals throughout the area. Two of the larger shoals intersect the pipeline in the southern half of the western area and extend into the eastern area. Other than the shoals, the seafloor is relatively flat in these areas, gently sloping to the southeast. The main shoals are generally oriented NW-SE with low relief in the intershoal areas.

The 2012 sampling event was limited in scope to the eastern two-thirds of PBP-OCS East due to a lack of geophysical data for PBP-OCS West. For the 2012 sampling event, one hundred (100) vibracores were cored in the PBP-OCS East area and only four (4) vibracores were cored in PBP-OCS West area. In August 2013, the USGS conducted a geophysical survey of PBP-OCS West and the unsurveyed portion of PBP-OCS East (Figure 4.2.1). It identified several large shoals that were then targeted during the 2013 sampling event. One hundred seventy-four (174) vibracores were taken in PBP-OCS West during the 2013 sampling event.

In PBP-OCS East, the more pronounced shoals are shorter, narrower, and more distributed throughout the area. Vibracores indicated that suitable thicknesses of acceptable borrow material are located along the crests of the shoals. Vibracores that are off the shoal crests indicate that the sediment typically does not meet the established standards from Section 3.0 for gradation or bedding thickness. These vibracores generally contained silty sand or a thin veneer of SP sand grading to silty sands and clays with increasing depth.

In PBP-OCS West, the results were similar to the eastern area in that the shoals tended to contain the largest concentrations of clean sand, while the off shoal areas tended to be silty sand to clay. One exception is the sandy fill deposit that extends from PBP-OCS West into PBP-OCS East, just north of large Shoal 3 (Figure 4.2.1.1) in PBP-OCS West. This deposit contains thick deposits of SP, but is covered

extensively by unsuitable overburden. There are small areas that have minimal overburden, which will be discussed further below.

Figure 5.2.11.1 shows the locations of PBP-OCS West and PBP-OCS East (solid blue outlines) and the 2012 and 2013 vibracore locations. The black dashed lines represent shoal outlines that were delineated by the USGS from their geophysical surveys. They illustrate the size and orientation of the shoals in each sampling area.

For the purposes of this report, PBP-OCS West and PBP-OCS East have been divided into smaller sub-areas because of their expansive sizes. The statistics presented are based on vibracore samples and are weighted by volume of borrow represented by samples.

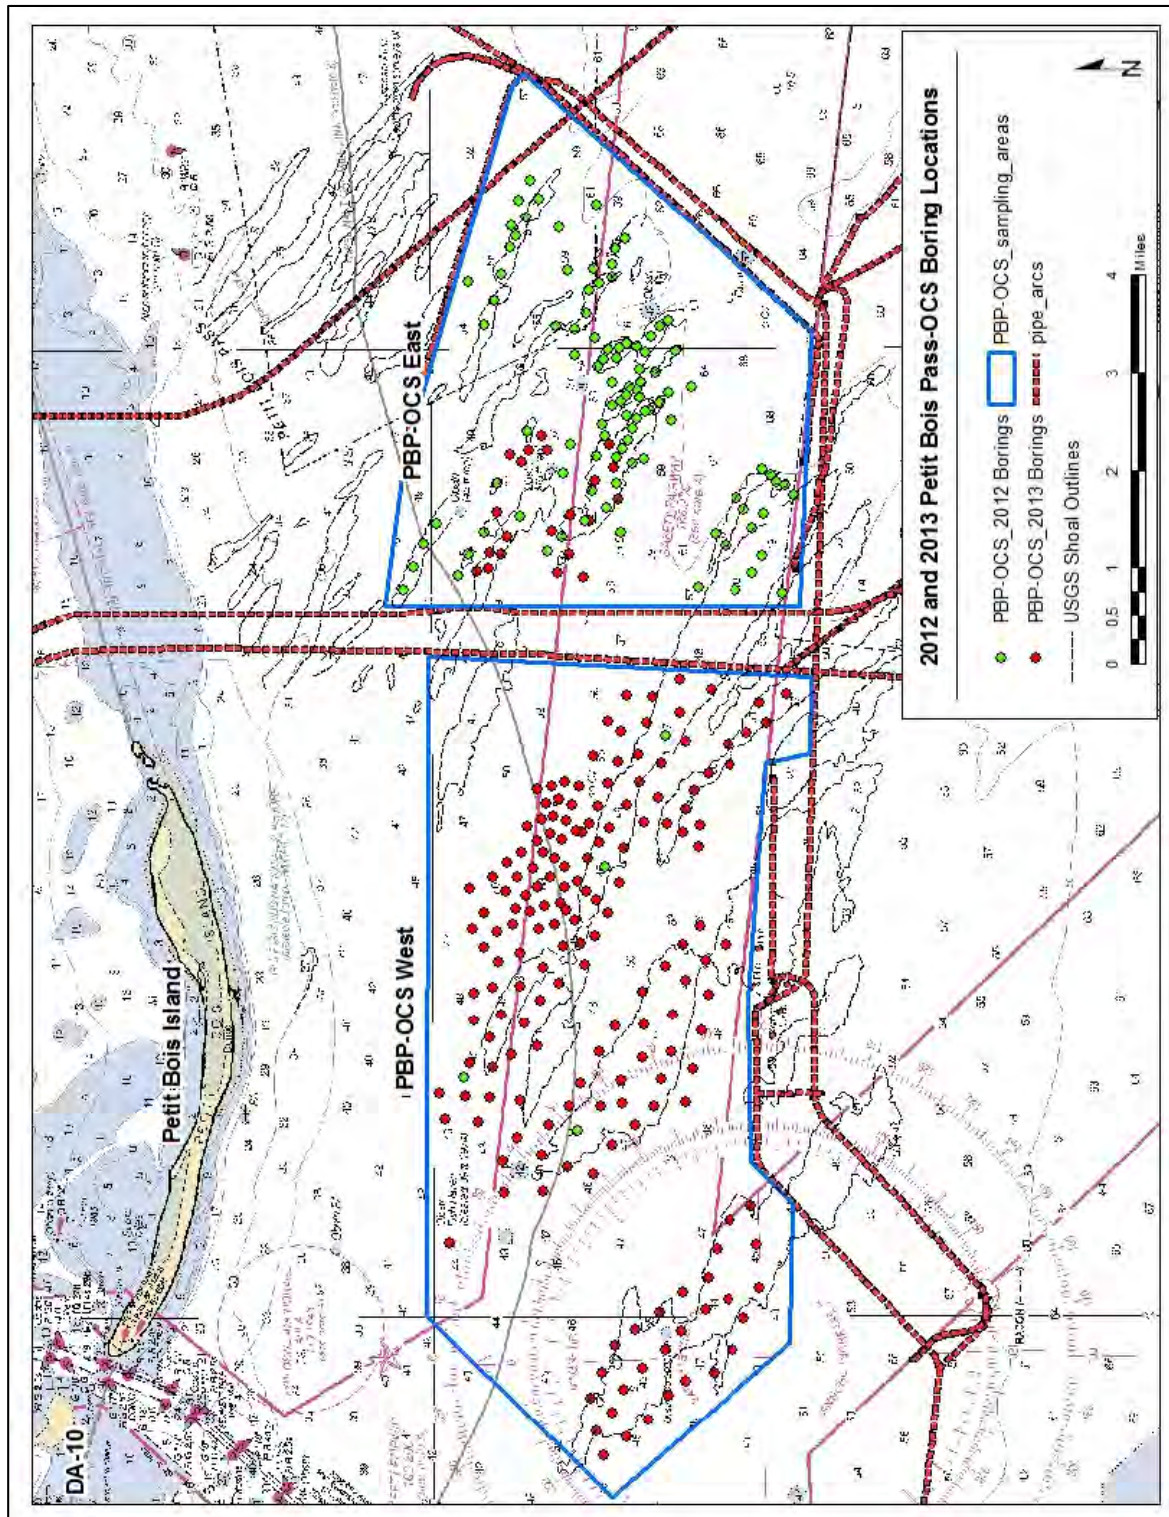

Figure 5.2.11.1 Petit Bois Pass-OCS sampling areas and vibracore locations.

## 5.2.11.1 PBP-OCS West Investigation Area

PBP-OCS West sampling area is approximately 4 miles south of Petit Bois Island. This sampling area is bounded by the north/south-running buried cable and pipeline to the east and the east/west-running pipelines to the south. This area contains three large shoals and a complex of smaller shoals in its southeast corner. Ambient water depths for the area range from 42 to 57 feet. Initially, the three major shoals were the focus of the 2013 sampling event because the geophysical survey data indicated they contained sandy substrates with minimal overburden. Table 4.2.1.1 contains a breakdown of the dimensions and textural characteristics of each shoal. The following sections discuss the results of the vibracore sampling during the geotechnical investigation.

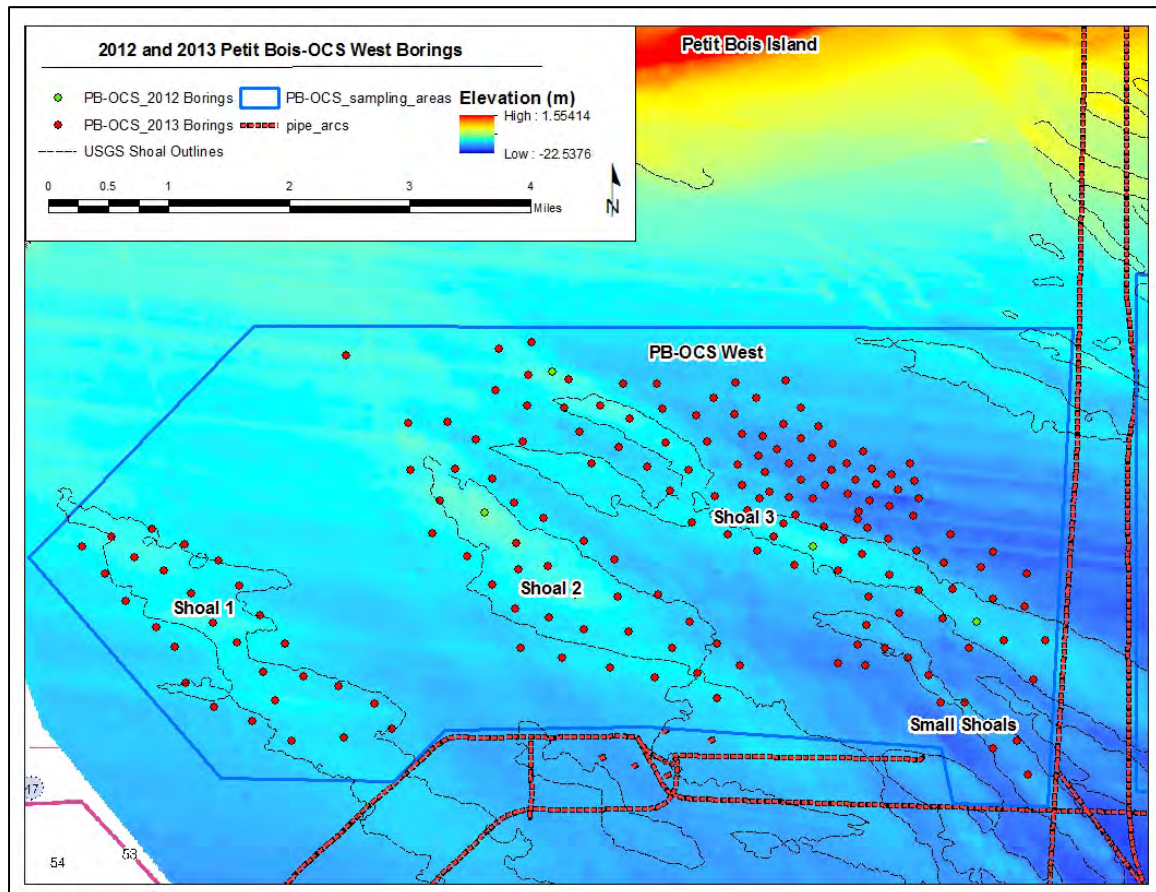

Figure 5.2.11.1.1 Petit Bois Pass-OCS West with major shoal outlines.

**Shoal 1:** Shoal 1 is a relatively low-relief feature (approximately 4-5 feet from shoal base to crest at the seaward end) located approximately 5.2 miles south of the western tip of Petit Bois Island (Figure 5.2.11.1.2). It is approximately 3.6 miles long, 0.7 miles wide at the northwest end, and 0.8 miles wide at the southeast end. Ambient water depths range from approximately 43 to 47 feet. The vibracores indicate that the shoal does contain significant sand deposits, ranging from 1.7 to 15.5 feet thick. However, composite D50 grain size for the vibracores in this area ranges from 0.14 mm to 0.25 mm, with an average of 0.18 mm. This grain size is too fine for the project and eliminates this area from further consideration as a borrow area.

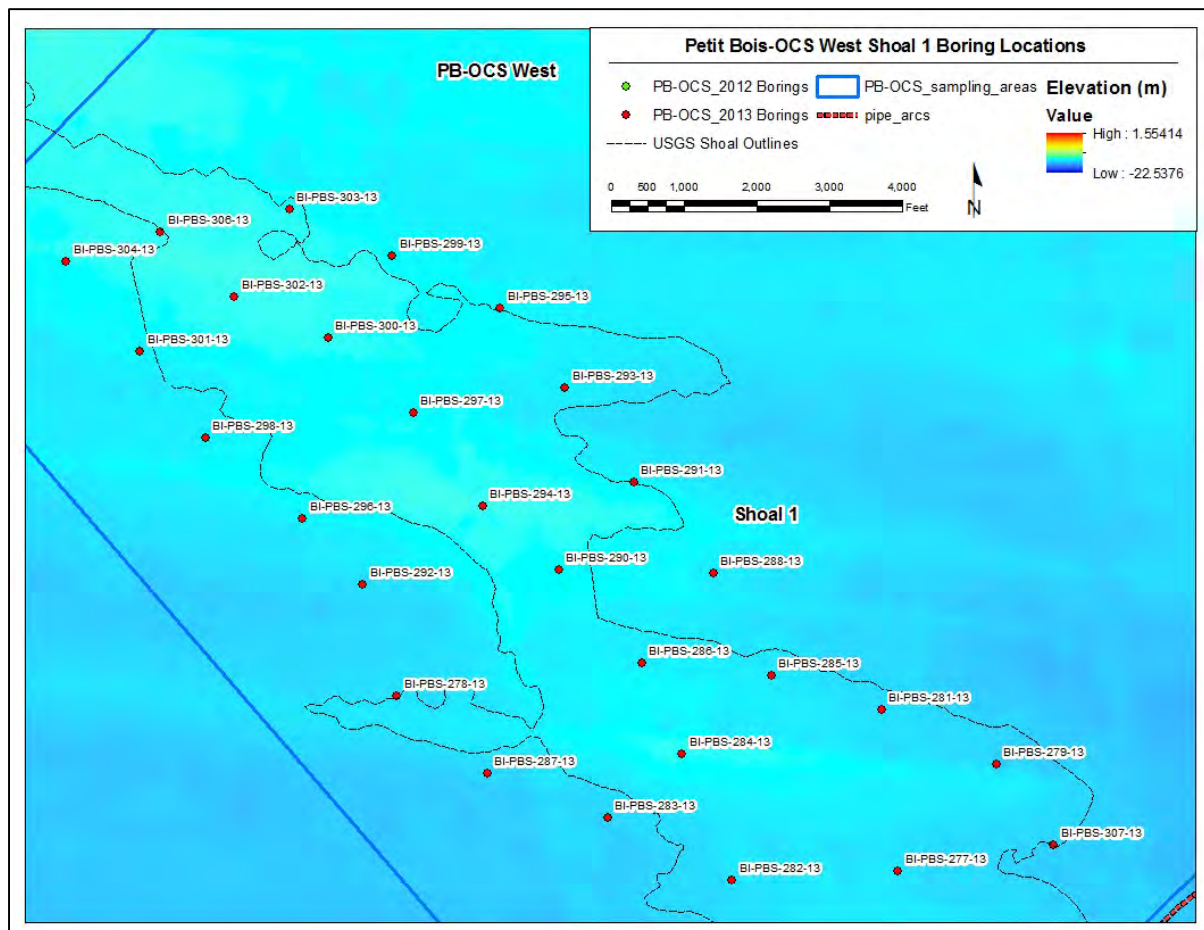

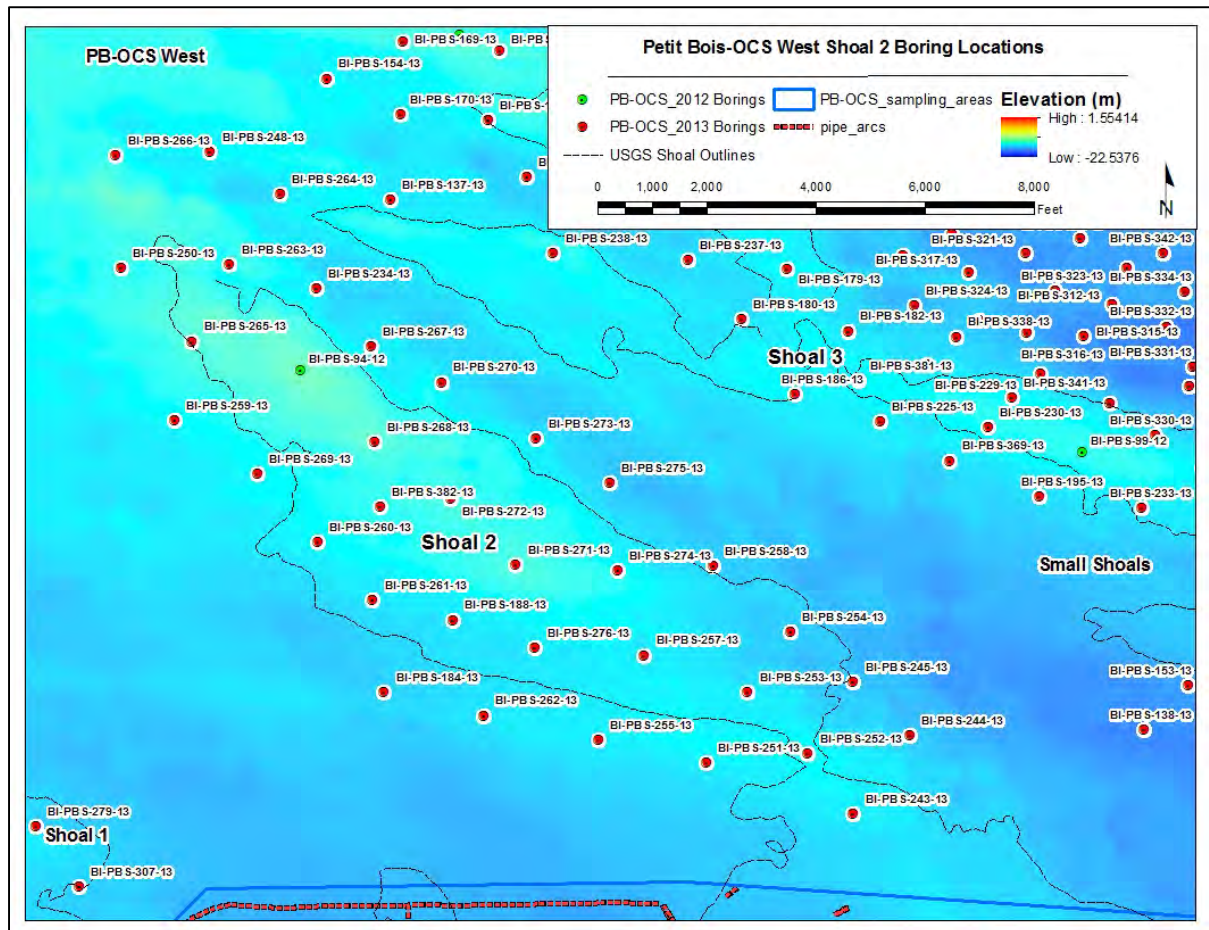

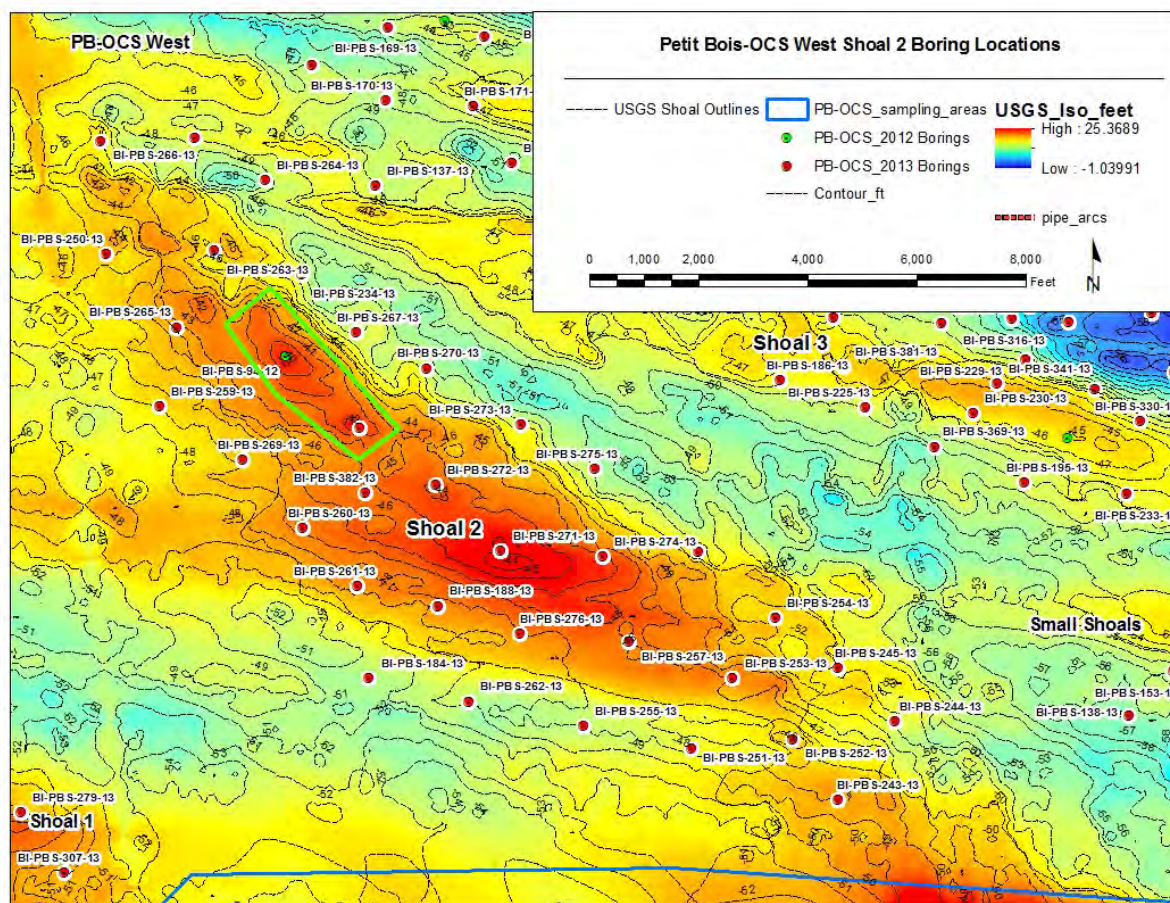

Figure 5.2.11.1.2 Petit Bois Pass-OCS West, Shoal 1 vibracores.

Shoal 2: Shoal 2 is located approximately 4 miles south of central Petit Bois Island and directly east of Shoal 1. It is approximately 3.8 miles long, 0.8 miles wide at the northwest end, and 0.7 miles wide at the southeast end. Its boundaries fluctuate throughout its length, making it appear to be composed of several smaller shoals. Ambient water depths in this area range from approximately 39 to 53 feet. It is slightly more pronounced bathymetrically than Shoal 1, ranging from 6 to 7 feet from shoal base to crest at the seaward end north of the pipeline. The shoreward face (northern side) has slightly steeper sides than the seaward face (southern side). The vibracores indicate that it has clean sand deposits with thicknesses ranging from 0.6 to 10.7 feet, and an average thickness of approximately 4 feet throughout the sampling area. The thickest exposed deposits are along the shoal crest. The composite D50 per vibracore ranged from 0.15 mm to 0.33 mm, with an average of 0.20 mm. The USGS's isopach for this area (Figure 4.2.2) does indicate that there is a thicker deposit of sand in the middle of the shoal. Two vibracores, BI-PBS-268-13 and BI-PBS-94-12, were sampled in this area and confirmed that the thickness and textural characteristics are adequate for dredging (Figure 5.2.11.1.4). A very small borrow area may be able to be designed using these vibracores as its center. D50 ranged from 0.25 to 0.26 mm and thickness ranged from approximately 8.3 to 10 feet. The area influenced by these two vibracores is approximately 85 acres, but could probably be expanded provided adequate mixing of dredged material is occurring to raise the composite grain size of the material. Cut thickness and area would need to conform to the bathymetry of the shoal. Sand deposits with suitable grain sizes surrounding these vibracores are typically only surficial and the sands tend to grade finer with depth. As a result, the cut depths required to get only the coarser sand may be too thin to be practical. Outside the two central vibracores, the majority of samples in this area indicate the sand is either too fine or too thinly-bedded for use with the project. Figure 5.2.11.1.4 outlines the location of these vibracores, which are underlain by the USGS's isopach for the shoal.

**Figure 5.2.11.1.3 Petit Bois Pass-OCS West, Shoal 2 vibracores.**

**Figure 5.2.11.1.4 Petit Bois Pass-OCS West, Shoal 2 with USGS Isopach showing potential borrow material vicinity vibracores BI-PBS-94-12 and BI-PBS-268-13.**

**Shoal 3:** Shoal 3 is located approximately 4 miles south of Petit Bois Island and less than 1 mile northeast of Shoal 2 (Figure 5.2.11.1.1). It is oriented northwest-southeast and is approximately 7 miles long, 0.9 miles wide at the northwest end, and 0.5 mile wide at the southeast end. It extends beyond the pipelines into the southwest corner of investigation area PBP-OCS East. It contains the greatest bathymetric relief of the three shoals within the sampling area, approximately 9 to 11 feet from shoal base to crest. Its landward face (north side) is steeper than the seaward face. It was initially sampled in 2012 in two locations, BI-PBS-99-12 and BI-PBS-101-12. Both vibracores indicated that the shoal has a veneer of poorly graded sand (SP) with trace shell hash underlain by silty sand that grades to clayey sand. Grain size typically grades finer with depth for the sands. The 2013 sampling event expanded on these vibracores to gain a better understanding of the shoal structure. Figure 5.2.11.1.5 shows the vibracores conducted on and around the shoal, with the majority of the shoal outlined with a pink polygon. Using the north-

south pipeline as a dividing line in the east, the western side of the shoal (in the PBP-OCS West investigation area) can be divided into three sub-sections based on its morphology.

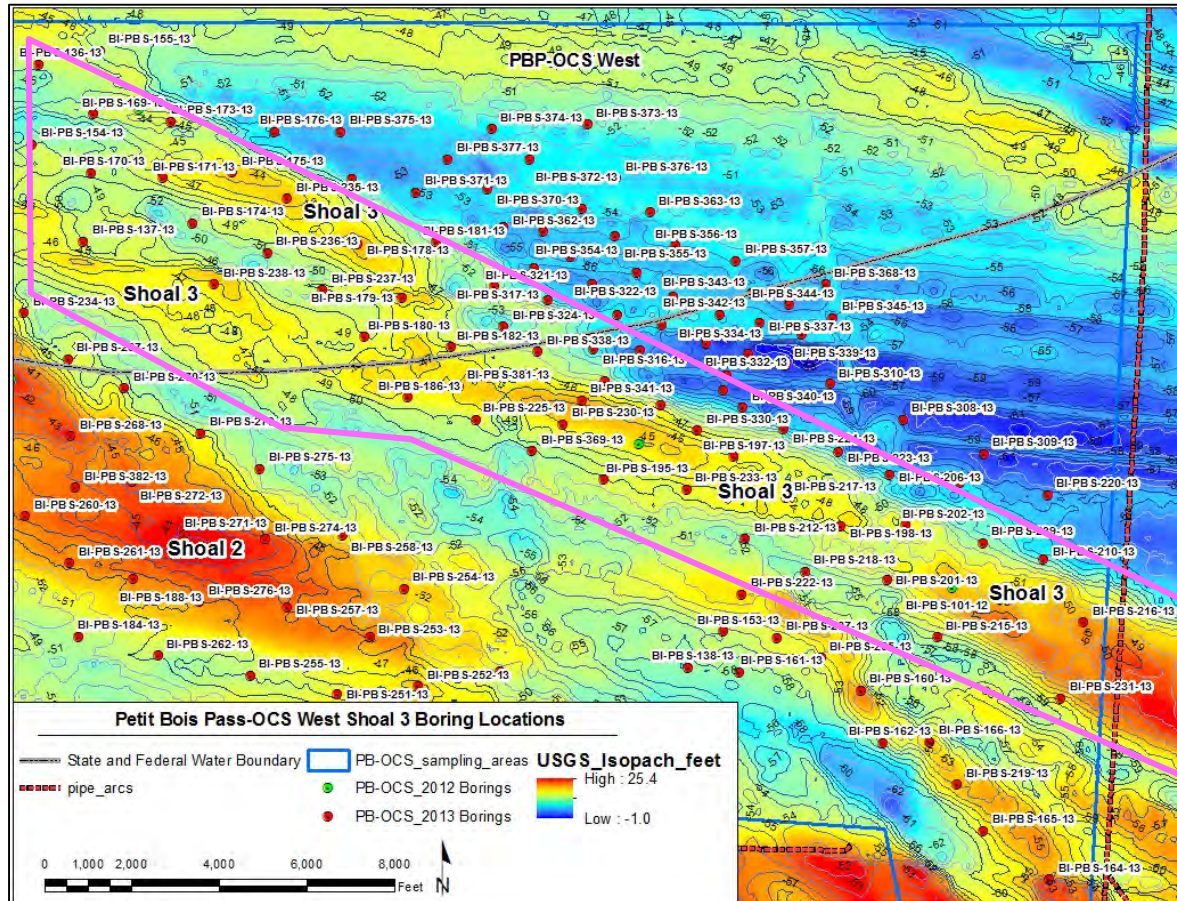

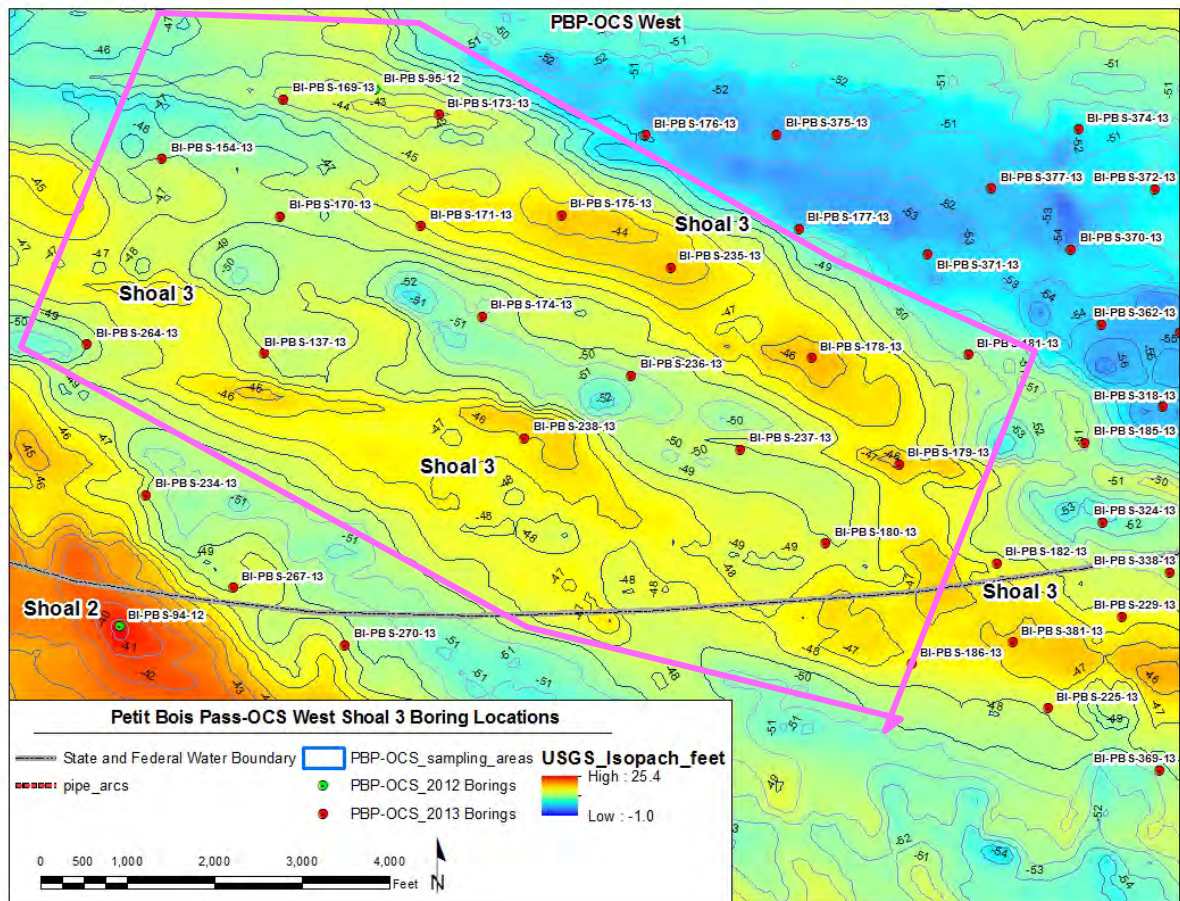

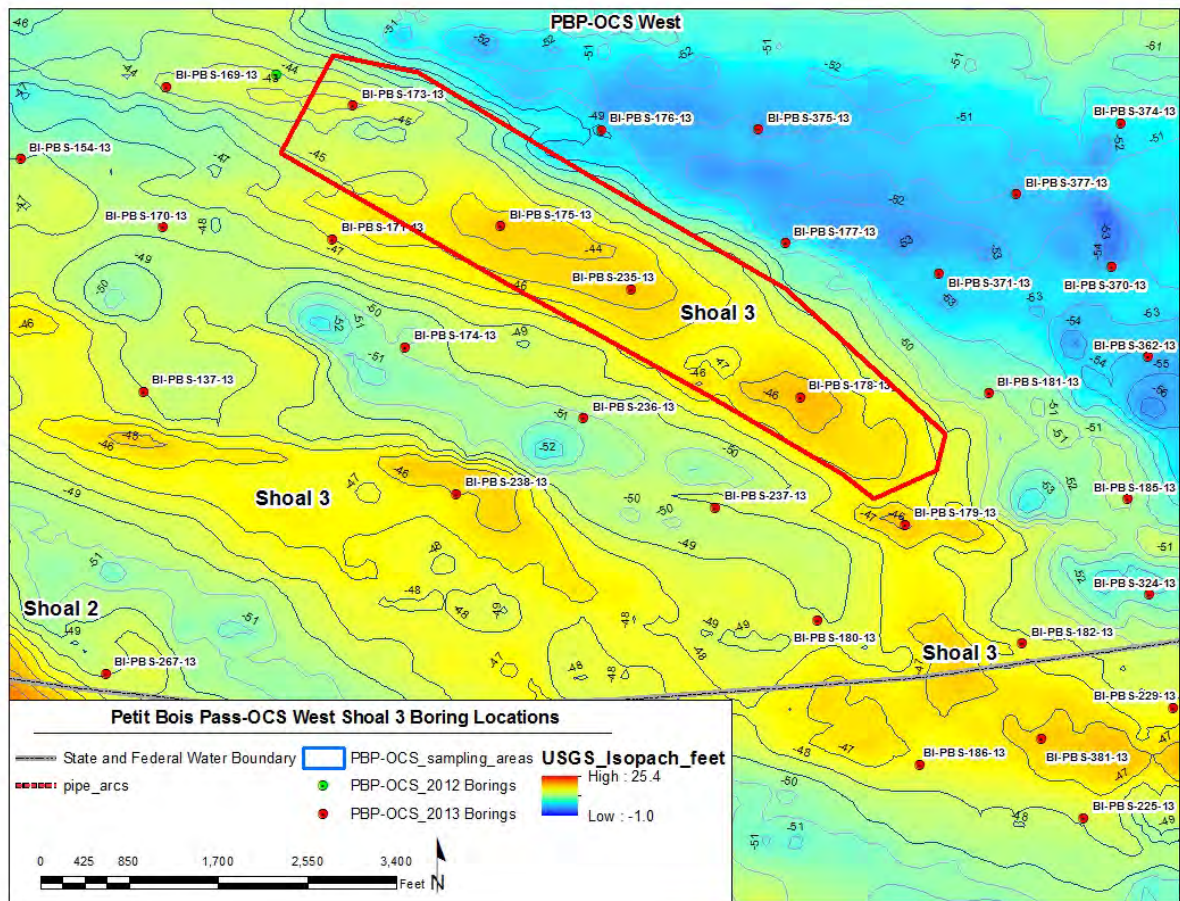

Figure 5.2.11.1.5 Petit Bois Pass-OCS West, Shoal 3 vibrocore locations.

Within the westernmost third (Figure 5.2.11.1.6), the shoal has a large trough dividing that section into northern and southern halves. Ambient water depths range from approximately 44 to 53 feet. Sampling in the northern half indicates that the shoal consists of a sandy deposit with adequate thickness and grain size for this project. The deposit spans the area from vibrocore BI-PBS-173-13 to BI-PBS-178-13 (Figure 5.2.11.1.7). Suitable sand thickness ranges from approximately 4.2 feet to 9.0 feet. The deposit is thickest at the shoal crest and tapers down at the side slopes according to the bathymetry and the USGS's isobath. Median grain size ranges from 0.26 to 0.28 mm within the vibrocores. Percent fines and color are also within acceptable limits.

**Figure 5.2.11.1.6 Western end of Petit Bois Pass-OCS West, Shoal 3 with USGS Isopach showing potential borrow material thicknesses.**

**Figure 5.2.11.1.7 Petit Bois Pass-OCS West, Shoal 3 (northwest side) suitable borings outlined in red.**

Suitable sand in the southern half is not as extensive. Vibracore BI-PBS-238-13 is located on the thickest portion of the southern half of the shoal and contains a 7.0 ft-thick layer of SP material. The grain size is borderline acceptable at 0.26 mm, but the color and percent fines are acceptable. The remainder of the vibracores along this portion of the shoal contain sand thicknesses ranging from less than a foot to 4.8 feet thick. However, grain size for these vibracores is too fine for use. This portion of the shoal is underlain by clay, typically at an elevation ranging from approximately -50 to -58 ft NAVD88. Geophysical data for the shoal does show that there is sandy material available, but the vibracore textural data along this portion of the shoal is too spread out to really determine whether this deposit contains suitable borrow material to make it feasible to mine.

The center area of the shoal contains more bathymetric relief than the northern third of the shoal. Figure 5.2.11.1.8 displays this portion of the shoal (pink line) with the

USGS isopach for the background. Ambient water depths range from approximately 45 to 56 feet. The isopach for the area (in feet) shows red where possible sand deposits are thickest and thins to blue. Greater sand thickness is evident on the shoal as anticipated, which correlates to the borings, but it is also thick off the northern side of the shoal (Figure 5.2.11.1.9) in the vicinity of borings BI-PBS-190-13 and BI-PBS-194-13. This thick deposit of sand, which extends to the north in this area, outlined in pink, was identified by the USGS's geophysical survey as being sandy fill in a relict Pleistocene distributary system. Ambient water depths range from approximately 50 to 59 feet. The strata consists of deposits of sand, silty sand, and clay in varying thicknesses and orientations. The clay stratum thickens to the south and west, terminating expansion in this area because, although the sand deposit on top of this clay has suitable characteristics, it thins out too much to be mined economically. Towards the north, the sand deposits become thicker and contain adequate grain size, percent fines, and color. There is a layer of overburden to the west and northwest that is too thick (>2 ft) to adequately mine the sand and still have composite textural characteristics that meet criteria (vic. BI-PBS-185-13). This overburden then thins out further north to expose an area with little overburden and adequate sand characteristics (vic. BI-PBS-361-13 to BI-PBS-334-13). Sampling indicates that the sandy deposit becomes finer grained towards the north and west, making expansion in this area not feasible due to grain size compatibility. Clay overburden thickens to the east and northeast, making it unfeasible to expand into this area. Based on these restrictions, the area directly adjacent to the shoal should be mineable, as well as the northwest-southeast sandy deposit located to the north of the shoal, extending from BI-PBS-361-13 to BI-PBS-334-13.

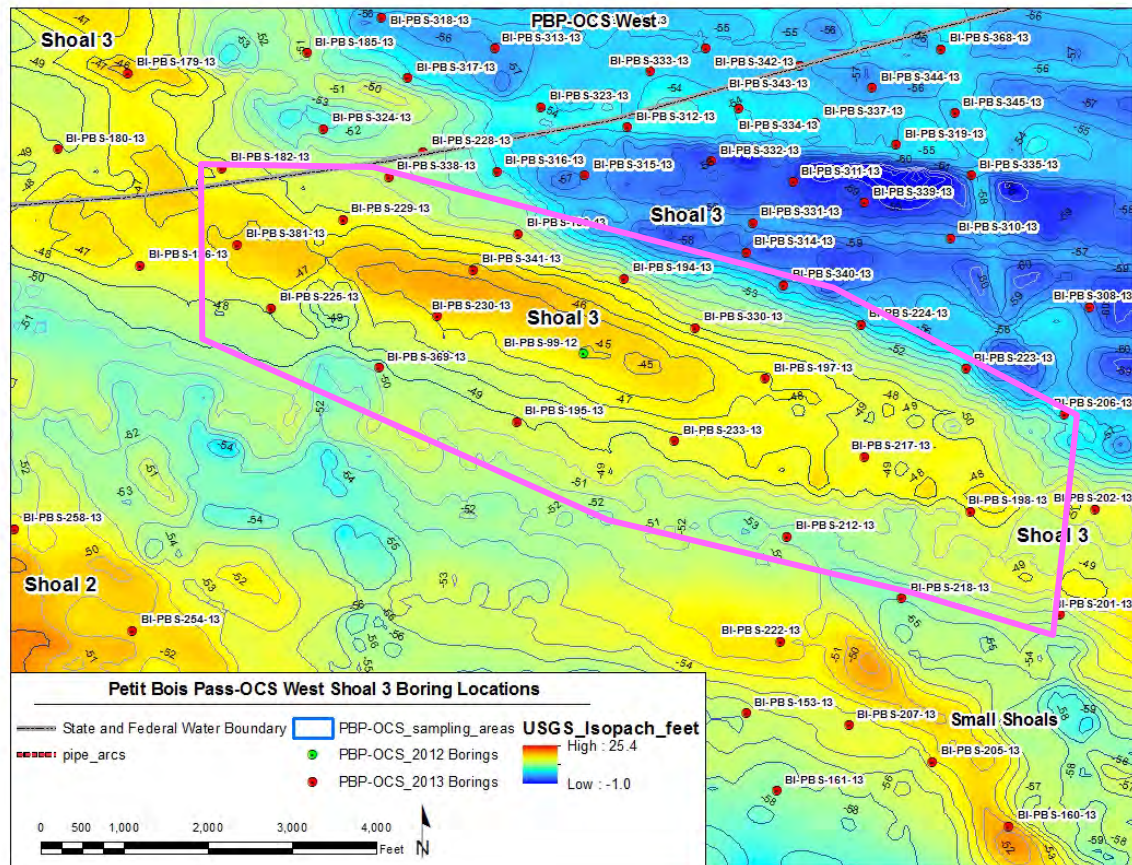

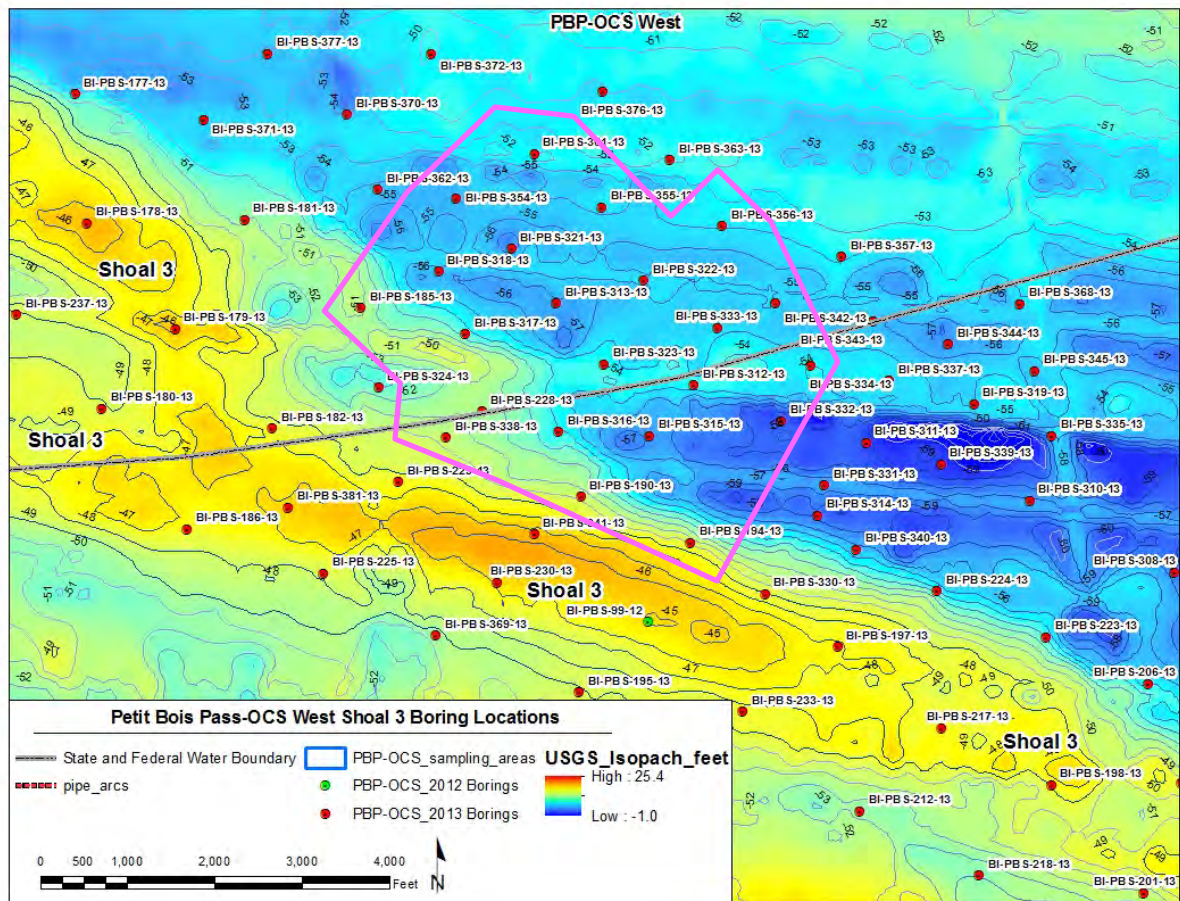

Figure 5.2.11.1.8 Central portion of Petit Bois Pass-OCS West, Shoal 3 with USGS Isopach showing potential borrow material thicknesses.

**Figure 5.2.11.1.9 Sandy fill area adjacent to central portion of Petit Bois Pass-OCS West, Shoal 3 with USGS Isopach showing potential borrow material thicknesses.**

The eastern portion of Shoal 3 extends past the pipelines and into the PBP-OCS East investigation area (Figure 5.2.11.1.10). The portion of the shoal immediately west of the pipelines was sampled in 2012 (BI-PBS-101-12) and appeared to contain an approximately 7.0 ft thick surficial deposit of sand over an equally thick deposit of clay. However, the 2013 sampling event has shown that the surficial sand deposit ranges from 1.2 ft to 7.7 ft. thick, depending on its location along the shoal. Ambient water depths range from approximately 48 to 57 feet. The thickest deposits are located along the crest of the shoal, tapering off to the sides. D50 grain size is coarsest along the crest of the shoal, ranging in the 0.28 to 0.31 mm size. Grain size typically decreases with depth of the deposit. Color and percent of fine sediments are also within suitable limits along the shoal crest. Unfortunately, the sand deposit is underlain by a clay deposit that is too thick (>2 ft) for deeper mining potential.

The easternmost portion of Shoal 3 is located approximately 6.1 miles southeast of the eastern tip of Petit Bois Island. It is bounded by pipelines to the west and south. Ambient water depths range from approximately 48 to 68 ft. Based on the vibracores, sand (SP) thicknesses on the shoal ranged from 1.2 to 11.3 ft, with an average thickness of 4.9 ft. Three vibracores along the crest of the thickest portion of the shoal contained sand thicknesses ranging from 8.1 to 11.3 feet, and a weighted average D50 of 0.27 mm. Their percent fines range from 1.3 to 3.0%. Its average dry Munsell Color Value is 6, with a typical dry Munsell color of light olive gray. It is slightly darker than preferred, but still acceptable sand. Borrow areas in both the eastern and western portions of this section of Shoal 3 are restricted to the shoal body, as vibracores indicate poor sediments outside of the shoal boundaries.

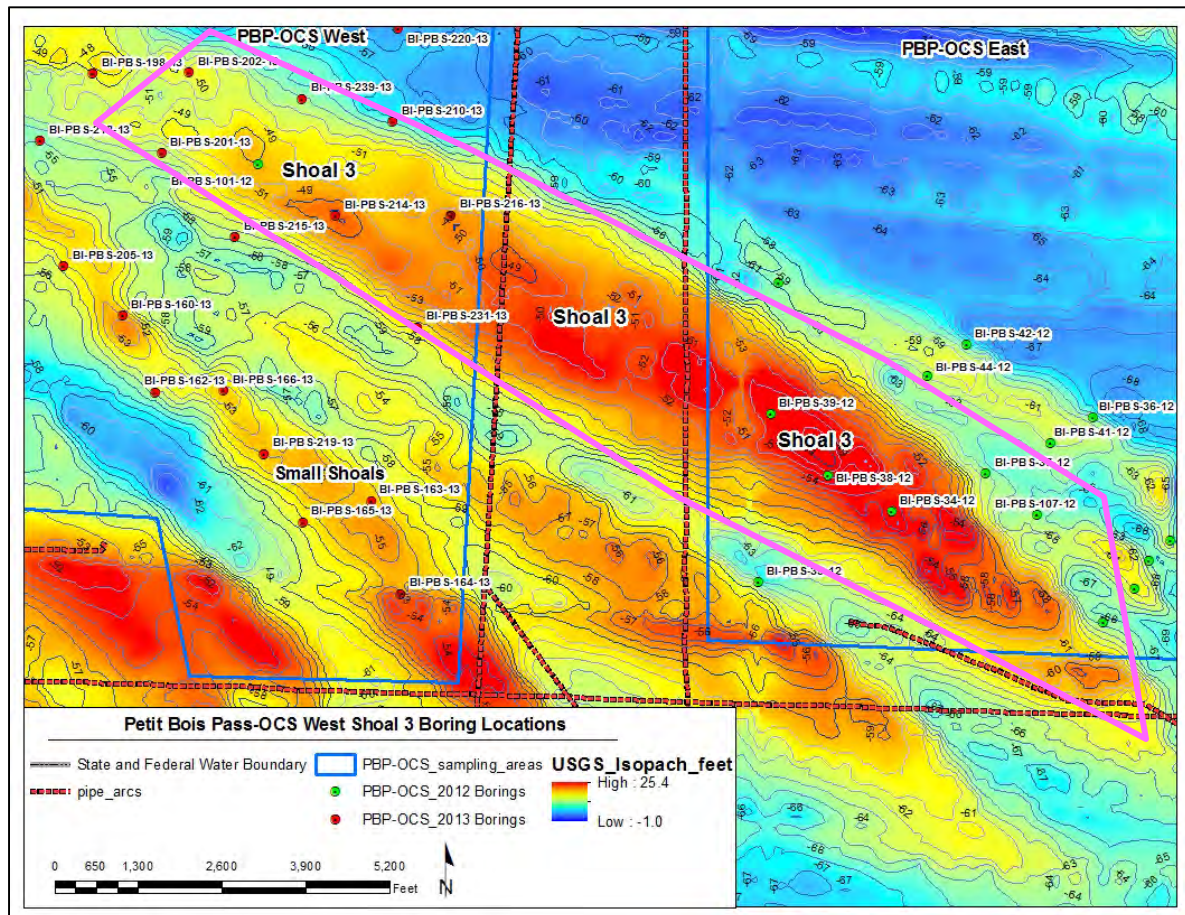

Figure 5.2.11.1.10 Eastern third of Petit Bois Pass-OCS West, Shoal 3 with USGS Isopach showing potential borrow material thicknesses. The shoal extends across two pipelines into PBP-OCS East investigation area.

## 5.2.11.2 PBP-OCS East Investigation Area

The PBP-OCS East investigation area is located approximately 5.5 miles south of the eastern tip of Petit Bois Island and immediately east of the two pipelines running north-south through Petit Bois Pass (Figure 5.2.11.2). This area is also bounded in the south and east by pipelines. The majority of this investigation area is located in Federal waters, with ambient water depths ranging from approximately 44 to 68 feet. There are numerous shoals located throughout the area, but the largest are located towards the center of the investigation area. Shoal 3 from the PBP-OCS West investigation area runs through the southwest corner of this investigation area. The remainder of the seafloor is relatively flat and has a gradual grade dipping to the southeast. Figure 5.2.11.2 shows the major shoals in the investigation area.

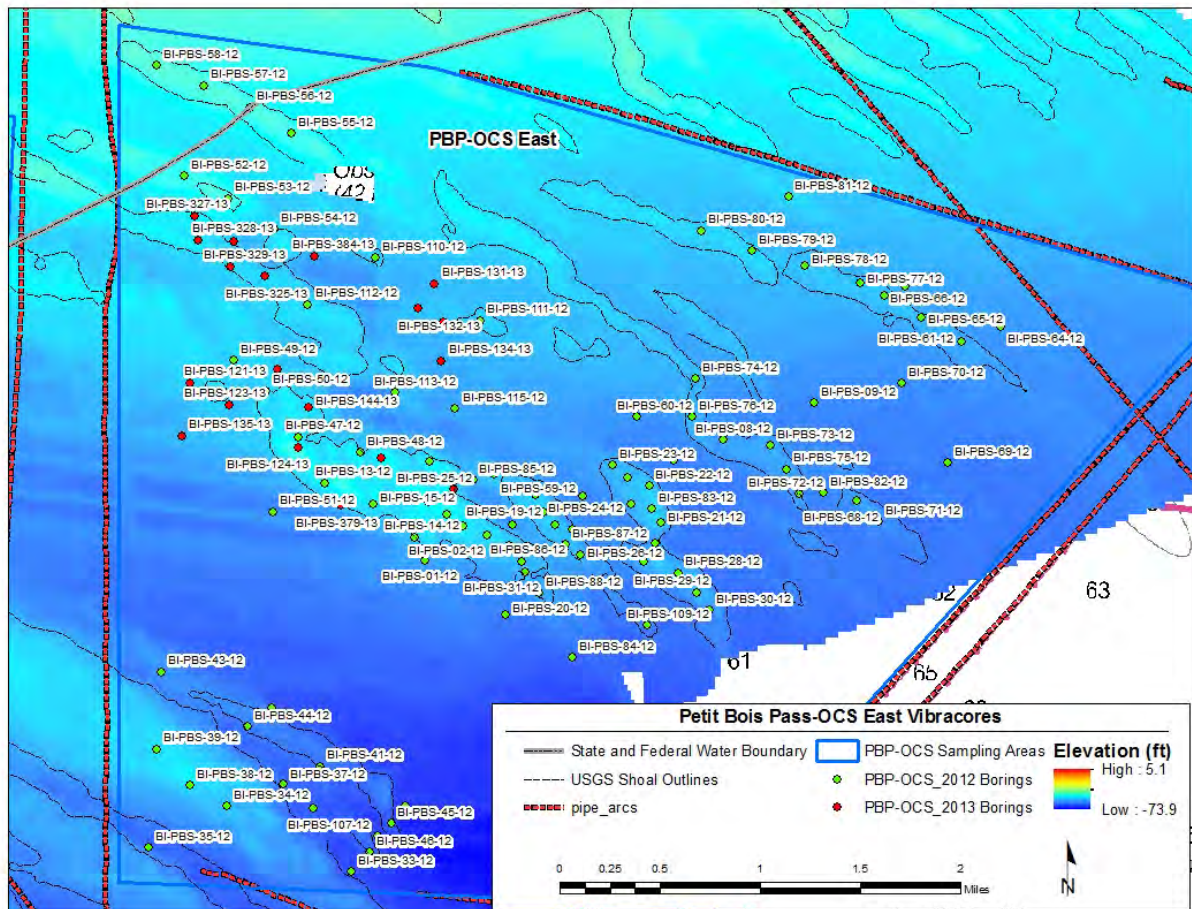

Figure 5.2.11.2 Petit Bois Pass-OCS East Investigation Area with vibracore locations.

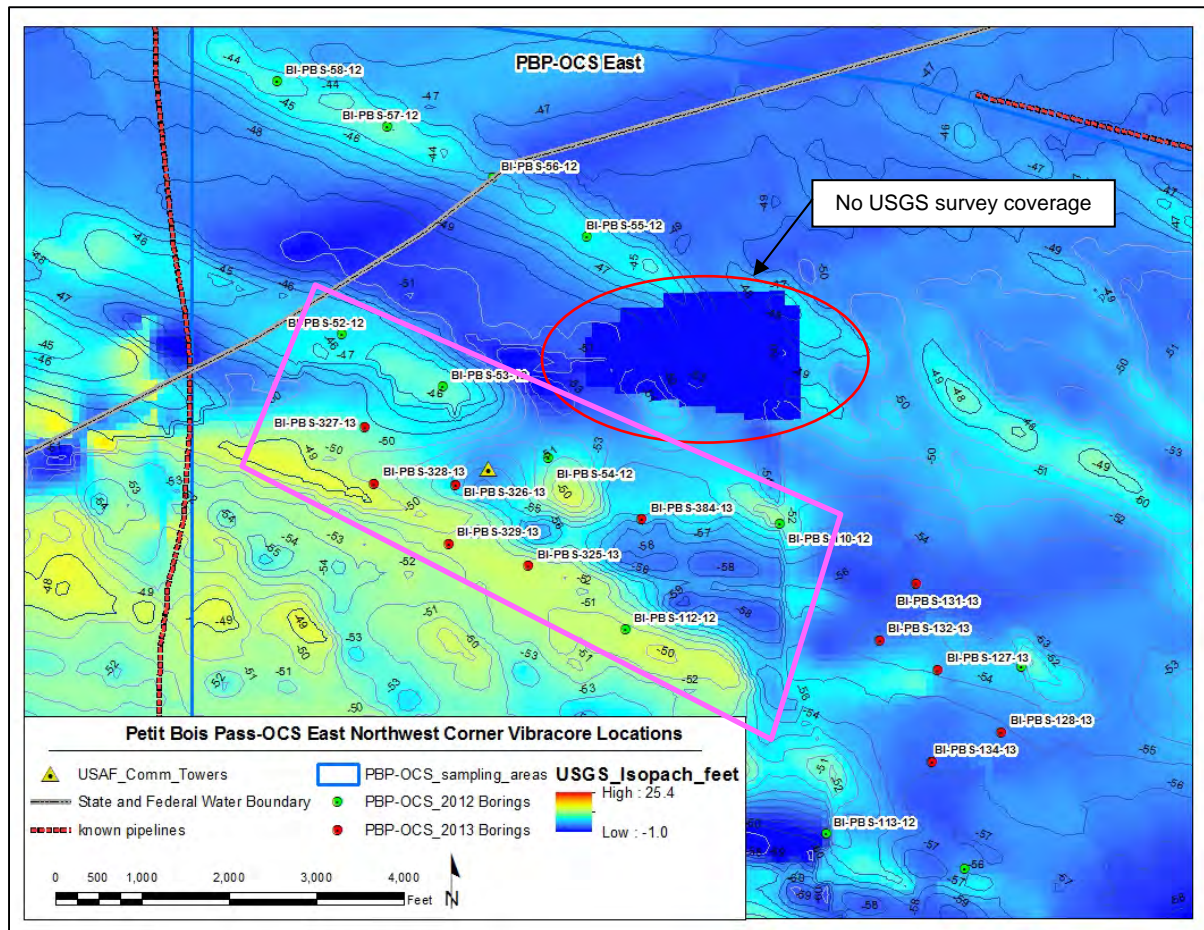

**5.2.11.2.1 PBP-OCS East, Northwest Corner**

The northwest corner of the PBP-OCS East Investigation Area is located approximately 4 miles southeast of the eastern tip of Petit Bois Island (Figure 5.2.11.2.1). Ambient water depths range from approximately 43 to 60 feet. Ten (10) vibracores were completed in this area in 2012 and an additional 16 vibracores in 2013. The intent of the sampling in this area was to investigate the smaller shoals indicated by the USGS' geophysical survey from 2010 and 2013. The background of the map in Figure 5.2.11.2.1 is the USGS' sand isopach for the area.

The four vibracores along the northernmost shoal (BI-PBP-OCS-55-12 through BI-PBP-OCS-58-12) contain a surficial layer of poorly graded sand (SP), underlain by clayey sand and then clay. Thickness of the SP layer ranges from 2.6 to 3.8 ft. D50 grain size ranges from 0.33-0.34 mm. Percent fines ranges from 1.4%-2.3%. Dry Munsell Color Value is 7 for all samples. Generally, grain size decreases with depth, while percent fines increases with depth. Color also typically becomes darker with depth. This area was not considered for further evaluation because the deposits are too thin for efficient dredging and they extend into Alabama state waters.

A larger shoal complex runs through the middle of the sampling area from the west just south of the shoal mentioned previously (pink outline in Figure 5.2.11.2.1). Three of the five 2012 vibracores contained suitable thicknesses of poorly graded sand ranging from 5.5 to 9.5 ft., and composite D50s of 0.33 mm, percent fines of less than 4% and typical dry Munsell Color of Light Gray with dry Munsell Value between 6 and 7. However, additional vibracores during the 2013 sampling event showed that the sediment along the shoal from BI-PBS-327-13 through BI-PBS-325-13 was too fine grained or too thinly bedded for use with the project. Vibracores directly east of this shoal indicate similar issues with fine grain size or thin bedding. Color is also darker in this area, with Munsell values hovering around 5 and 6.

A U.S. Air Force communications tower is located between BI-PBS-326-13 and BI-PBS-54-12. It requires a specific buffer to avoid accidental damage during construction and would affect borrow area perimeter shape.

**Figure 5.2.11.2.1** Completed vibracores for the northeast corner of the Petit Bois Pass-OCS East investigation area with USGS sand isopach as background. Note: there is a U.S. Air Force communications tower (yellow triangle) in the area that requires a buffer.

#### 5.2.11.2.2 PBP-OCS East, Central Shoal Complex

The PBP-OCS East central shoal complex is located approximately 5.7 miles southeast of the eastern tip of Petit Bois Pass-OCS Island. Ambient water depths range from 44 to 63 ft. There are three major northwest/southeast-running shoals displaying significant sandy substrate thicknesses in this area based on the USGS' geophysical survey. The off-shoal area consists of gently undulating seafloor dipping generally towards the southeast. Vibracores in this area primarily targeted the four shoals, with some taken off-shoal to determine if there are any significant buried paleo channels. Within the vibracores, grain size typically decreases with depth, while percent fines increases with depth. Also, color typically becomes darker with depth, usually as a consequence of increasing fines. Sand bed

thickness decreases considerably off the shoals. Figure 5.2.11.2.2 shows the vibracores taken in the area.

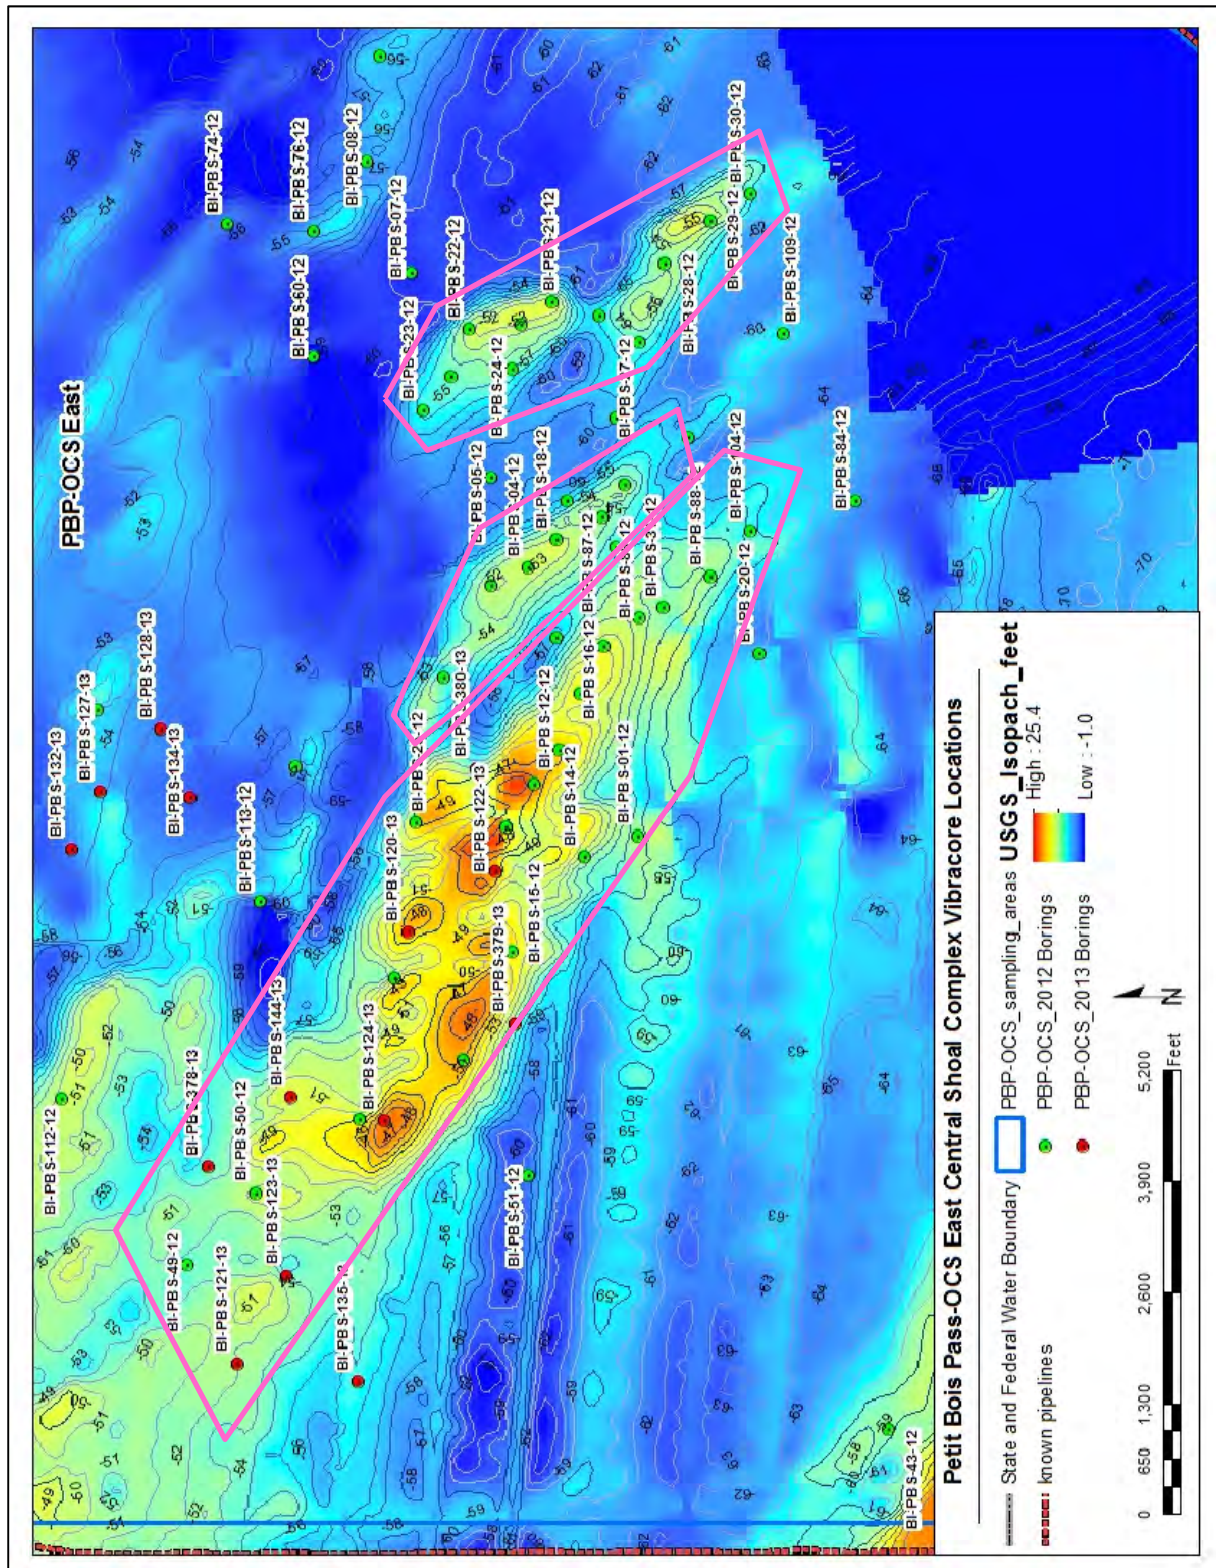

Starting with the western shoal, the vibracores contained a surficial layer of poorly graded sand (SP), with thicknesses ranging from 0.4 to 10.4 ft. with an average thickness of 5.1 ft. and composite D50 grain size ranges from 0.20 to 0.37, with an average D50 of 0.26 mm. Percent fines range from 1.2% to 14.5%, with an average of 4.7%. Dry Munsell Color Value ranges from 5 to 7.5, with a typical light gray color.

The middle shoal's vibracores contained SP thicknesses ranging from 1.0 to 8.6 ft with an average thickness of 4.7 ft. Composite D50 grain size ranges from 0.21 to 0.5 mm, with an average D50 of 0.30 mm. Percent fines range from 1.7 to 3.8% with an average of 2.5%. Dry Munsell Color Value ranges from 6 to 7, with a typical light gray color.

The eastern shoal's vibracores contained SP thicknesses ranging from 2.3 to 7.7 ft., with an average thickness of 4.9 ft. Composite D50 grain size ranges from 0.17 to 0.66 mm, with a weighted average D50 of 0.30 mm. Percent fines range from 2.2 to 14.9%, with an average of 5.4%. Dry Munsell Color Value ranges from 5 to 7, with a typical light gray to light olive gray color.

The thickest portions of sand correspond with the shoal crests. Off the shoals, the vibracores indicate a drastic reduction in the thickness of sandy deposits. This corresponds with the geophysical survey results from 2010 and 2013. Typically, D50 grain size also begins to grade smaller in the more southern shoals.

**Figure 5.2.11.2.2 Completed vibracores for the Petit Bois Pass-OCS East central shoal complex with bathymetric contours illustrating the main shoals in the area.**

## 5.2.11.2.3 PBP-OCS East, Eastern Shoals

The eastern shoals in PBP-OCS East are located approximately 5.9 miles south of the western tip of Dauphin Island. The majority of the area consists of gently sloping seafloor with a series of very small northeast-southwest oriented shoals. Of the 10 vibracores on and around the largest shoal, only two have a sand (SP) thickness greater than 4 ft (BI-PBS-76-12 and BI-PBS-68-12). Thicknesses range from 2.2 to 4.2 ft, with an average of 3.3 ft. D50 grain size ranges from 0.19 mm to 0.34 mm, with an average of 0.24 mm. Percent fines range from 2.7 to 13.3%, with an average of 8.2%. Dry Munsell color value ranges from 5 to 7 with a typical color of light gray to light olive gray.

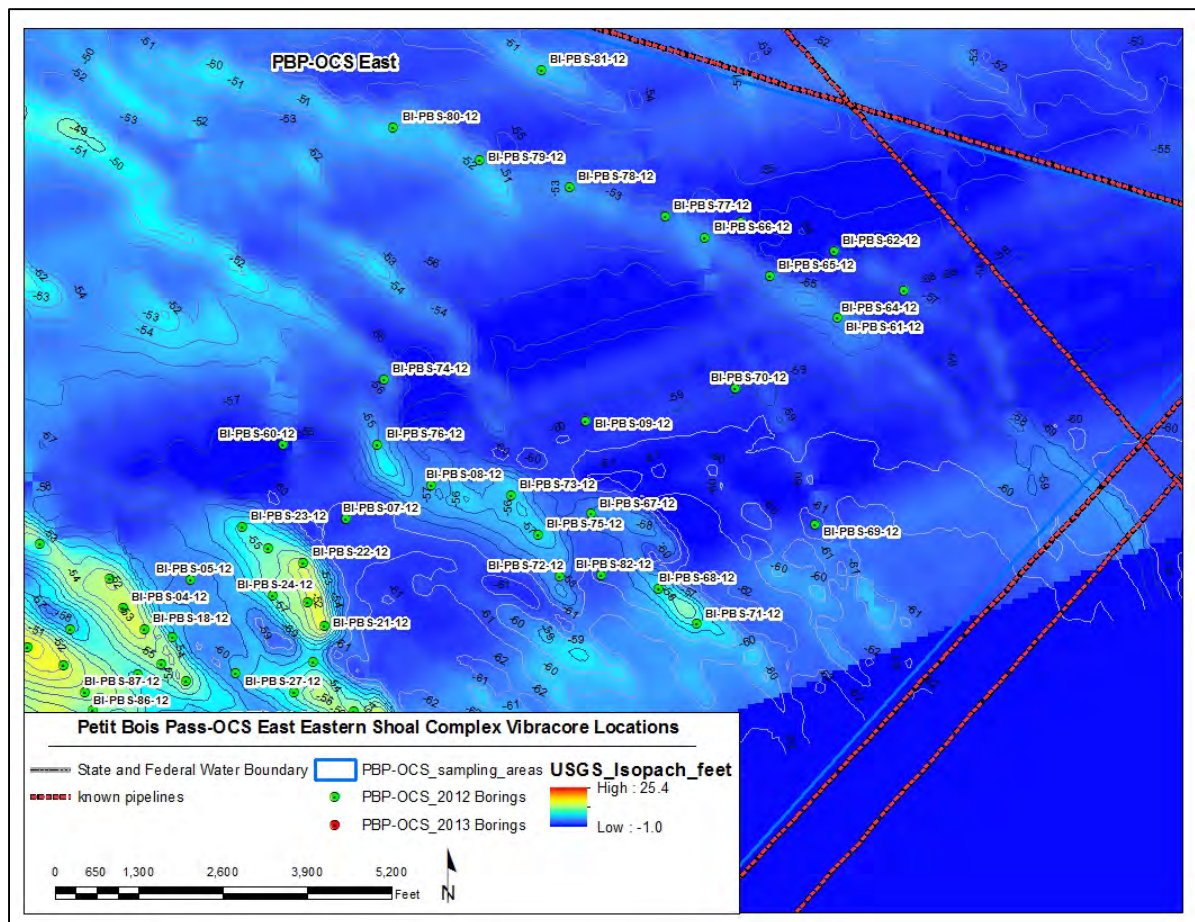

Figure 5.2.11.2.3 Completed vibracores for the Petit Bois Pass-OCS East eastern shoals investigation sub area with the USGS' isopach illustrating sandy substrate thicknesses.

There are no significant shoal features in the northeast section of PBP-OCS East, approximately 4.8 miles south of the western end of Dauphin Island. Ambient water depth ranges from 52 to 57 ft. Each of the vibracores in this area had a surficial layer of sand (SP), ranging in thickness from 0.8 to 3.2 ft. Within this veneer, D50 ranges from 0.18 mm to 0.32 mm, with an average D50 of 0.26 mm. Percent fines ranges from 1.6% to 11.6%, with an average of 5.1%. Its average dry Munsell Color Value is 6, with a typical color of light olive gray to light gray. Two vibracores, BI-PBS-62-12 and BI-PBS-63-12, had beach quality sand beneath silty and clayey sand layers. Unfortunately, these SM and SC layers are too thick (2.3 and 5.8 ft, respectively) for these to be considered feasible for borrow. In addition, the vibracores in the western half of this area were underlain by clay and silt, not sand. This area is not suitable for borrow material.

## 6.0 BORROW AREAS

Borrow area delineation is a complex task which requires balancing all available geological, hydrological, archaeological, and environmental constraints for a given site to maximize potential yields. It is an iterative process and is not necessarily linear, but the following descriptions outline the overall processes and tasks followed for the borrow area designs.

- Geophysical surveys are conducted to provide a large scale view of the geology in a particular study area and can identify potential sand bodies. They provide a subsurface view of a potential borrow area and can indicate the areal extent, thickness, and orientation of a sand deposit. They assist with identifying the horizontal and vertical boundaries of a delineated borrow site. They are somewhat limited in that they do not always “see” clay or silt layers and sediment sampling is necessary to physically validate their models.
- Vibracore samples are used to validate and improve the geophysical survey’s stratigraphic model and provide textural data (e.g. grain size, color, angularity, and fine sediment content) for the sediments in the different strata. They provide the ground-truth of what sediments are actually there and dictate if a sand body meets the established textural requirements for borrow material. They assist with data gaps when the geophysical survey cannot see certain strata due to the material type, e.g. clays, or subsurface gas (Figure 4.1.1.2).
- Bathymetric surveys provide the actual seafloor surface elevations for use in shaping the borrow area and determining dredge cut elevations and borrow quantities. These surveys are especially important for areas of varied relief, such as the area south of Petit Bois Island, where suitable sand deposits are contained mostly within the confines of shoals and the borrow area must conform to the shape and orientation of the shoal. The bathymetry also helps to understand the effects the borrow area’s side slopes will have on the areas adjacent to them.
- Archaeological surveys identify any potential objects of anthropogenic significance that must be avoided within the proposed borrow area. This can result in the borrow area either being reconfigured with a buffer around the object, or complete elimination of the site if the buffer proves too large for the area to be economically feasible to mine.
- Modeling is conducted on potential borrow sites that may potentially affect landforms or man-made structures post-dredging through wave-focusing or other altered hydrodynamic processes. The modeling gives an indication if the borrow area needs to be repositioned or reconfigured to reduce its influence.

- Thiessen polygon analysis is used to map each boring's influence on the sediment characteristics within the borrow area. This analysis gives the designer an idea of the shape needed to statistically maximize a particular boring's textural characteristics. This analysis technique works best on low relief areas. It does not do a good job accounting for inconsistent, undulating surfaces, like shoals, because the boring could be at the base of the feature and not have any effect on the top of the feature, even though the Thiessen polygon says that it should. However, this analysis technique offers a good starting point for determining borrow area shape in the absence of distinct geomorphic features that might otherwise dictate shape.
- Areal boundaries are drawn to best fit the extent of the suitable sand deposit, given the constraints identified by the geophysical survey, the vibracores, and the bathymetric and archaeological surveys. Subareas, or cells, are designed, as necessary, to optimize the dredgeable quantity within these boundaries by altering cut elevations to fit the deposit's orientation and thicknesses. Dredge equipment capabilities are another constraint that factors into the borrow area design. In particular, the bottom cut elevation needs to be adjusted to accommodate overdepth dredging caused by human error, environmental conditions, or mechanical limitations. Overdepth dredging can result in unsuitable material being dredged. Because of the difficulty in designing a borrow area on a convex surface such as a shoal, there are areas that are considered allowable dredge material, but not required for the project. The purpose of these allowable areas is to recognize that the material is suitable for the project, but that the difficulty in dredging it could increase project costs for the contractor. By making it optional, the contractor can decide if the cost is worth the effort to ensure the required quantities for the fill specifications are met. Several borrow areas have "Allowable" borrow cells. After the boundaries are established, volumes of the sand can be calculated for each area and subarea using software such as InRoads or ArcGIS. The textural characteristics of the sediment can then be calculated for each borrow area to ensure they meet the fill requirements established at the beginning of the investigation.

Using this process, USACE Mobile identified several potential borrow areas. The shape and dimensions of the borrow areas have been configured to maximize sand recovery while minimizing environmental impacts. Dredge equipment capabilities have also been considered in the designs. The following figures do not necessarily represent the final designs for the borrow areas, as future surveying or other pre-construction data may necessitate changes. Table 6.1 contains the current borrow area statistics.

Cat Island, Ship Island, DA-10, and Petit Bois Pass-AL East and West borrow areas have been modeled and their boundaries identified. Using their updated shapes and

projected dredging cut elevations, their projected volumes have been calculated using Bentley's InRoads software program. Area dimensions do not include the footprint of the estimated fall-in of the side slopes after dredging. Table 6.1 summarizes this information.

**SECTION 6****Offshore Sand Borrow Investigation, 2010-2014  
Identified Borrow Areas****Table 6.1 Borrow Area statistics**

<b><i>Borrow Area</i></b>	<b><i>Template Volume (mcy)<sup>2</sup></i></b>	<b><i>Area (Acres)<sup>3</sup></i></b>	<b><i>D50 (mm)</i></b>	<b><i>Percent Fines</i></b>	<b><i>Dry Munsell Value</i></b>
Petit Bois Pass-Alabama East	14.7	885	0.33	7	6
Petit Bois Pass-Alabama West	5.1	380	0.31	4	6
Petit Bois Pass-Mississippi	2.0	175	0.31	3	7
Petit Bois Pass-Outer Continental Shelf East	4.2	464	0.29	2	7
Petit Bois Pass-Outer Continental Shelf West	15.4	1,383	0.27	3.4	6
Horn Island Pass	4.9	612	0.28	4.4	7
Ship Island	2.7	183	0.21	6	7
Ship Island Pass <sup>1</sup>	0.45	20.9	0.48	< 1	6
Cat Island	4.3	429	0.20	5	6
Total	53.7				

<sup>1</sup>Ship Island Pass borrow material D50 and percent fines is derived from a proxy sample taken from the north shore of West Ship Island (see Section 5.2.4 Ship Island Pass for discussion).

<sup>2</sup>Borrow area template volume does not include estimated losses caused by dredging inefficiencies. Template volume includes the estimated required dredge volume and the estimated allowable dredge volume.

<sup>3</sup>Borrow area acreages are estimated based on cut bottom area and do not include side slopes.

## Cat Island

The design for the Cat Island borrow area been an iterative process due to wave and hydrodynamic modeling, coupled with expansion for additional material. Figure 6.1 shows the latest proposed borrow area. Its location is far enough offshore and its cut depth is relatively shallow to reduce significant wave focusing on the island. The new borrow area is separated into two cells with cut elevations of -18.5 feet NAVD88 (northeast half) and -19.5 feet NAVD88 (southwest half). Areally, it is approximately 1650 feet wide (northwest-southeast) by 10,100 feet long (northeast-southwest) and covers approximately 429 acres combined with an estimated volume of 4.3 mcy at an average cut depth of 5 feet. It has an average D50 of 0.20 mm and a dry Munsell value of 6. The average percentage of fines is expected to be 5%. Its grain size is finer than the original goal of 0.28 mm, but the close proximity to the island and the fact that the sand is being placed mostly on existing land rather than an open water cut, led to the design and use of this borrow area.

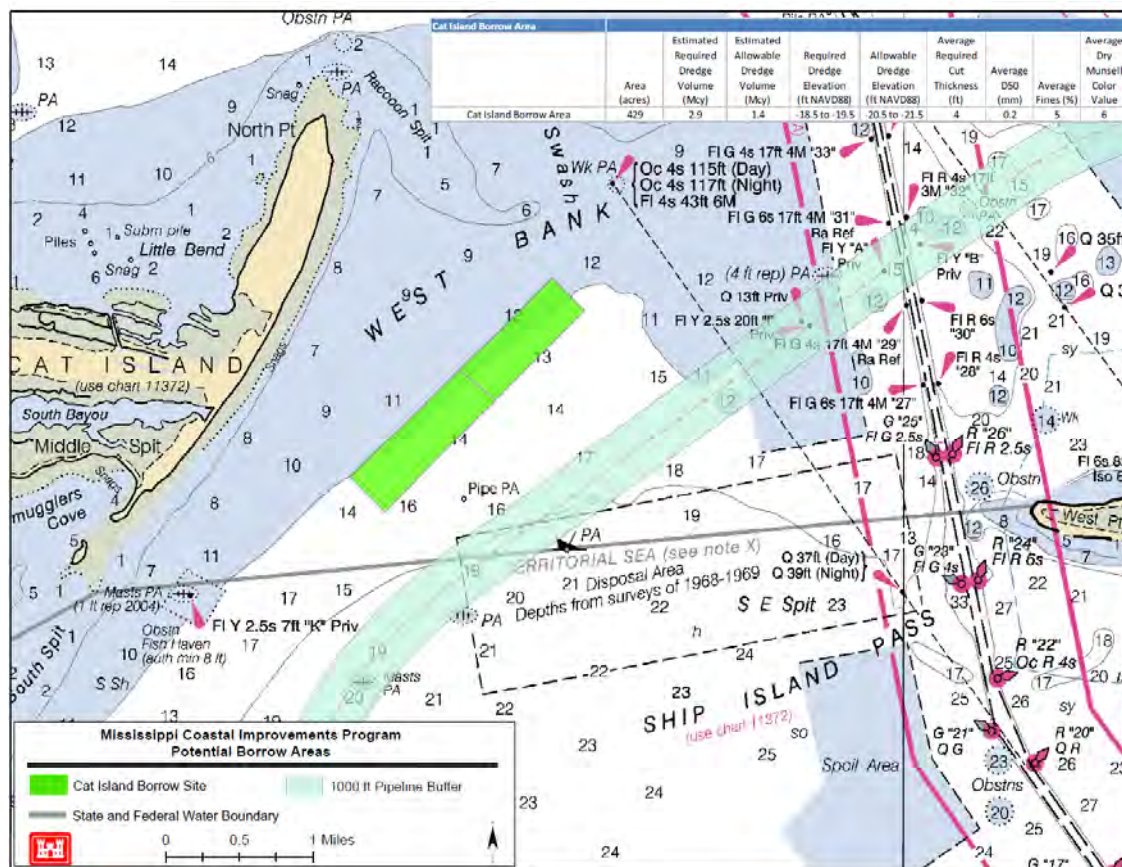

Figure 6.1 Cat Island Borrow Area

## Ship Island Pass

As discussed in Section 5.2.4, material for placement on the north shore of West Ship Island was identified at the western end of the island, in the vicinity of the old Gulfport navigation channel. Figure 6.2 shows the final location, orientation, and general shape of the borrow area used for the nourishment. The borrow area volume is estimated at approximately 450,000 cy with an area of approximately 20.9 acres. The proxy D50 grain size is 0.48 mm and the dry Munsell value is 6. The average percentage of fine material was approximately 1%.

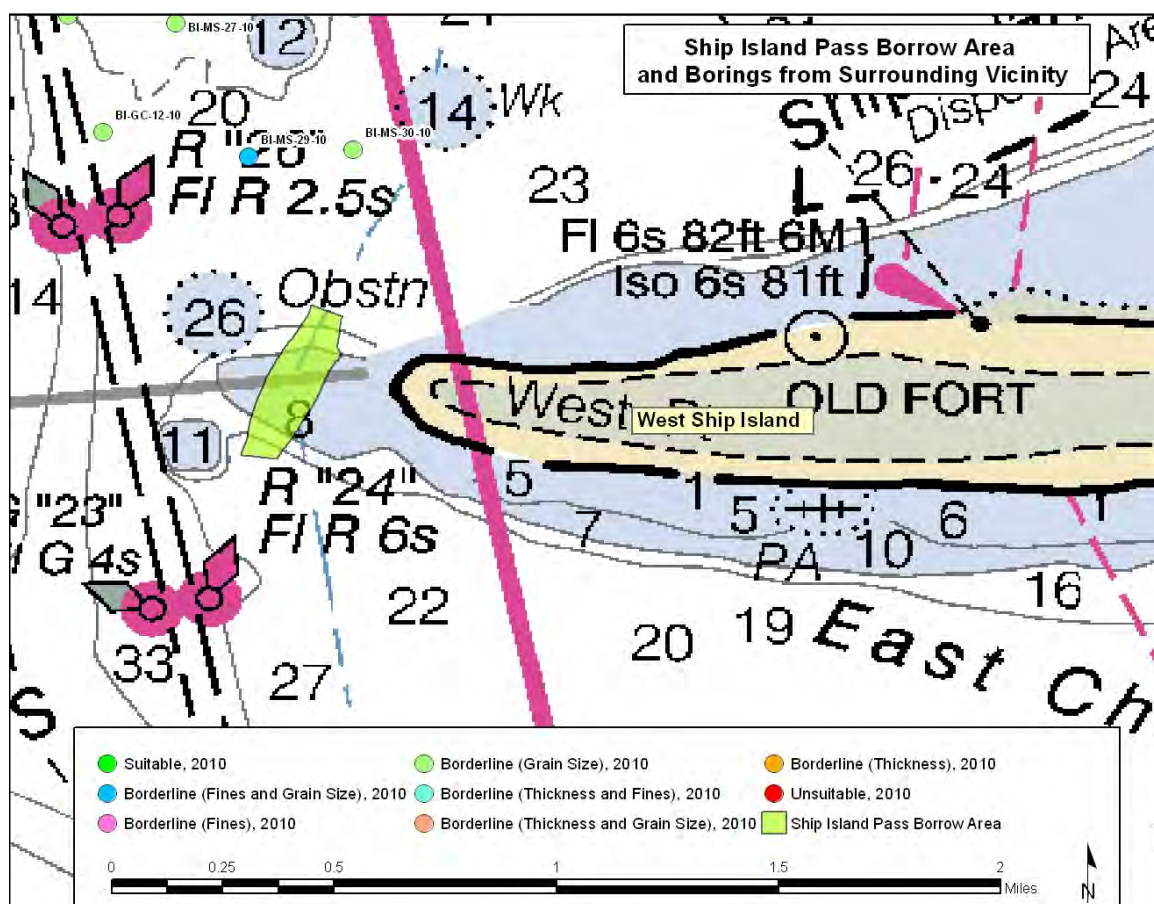

Figure 6.2 Ship Island Pass Borrow Area for north shore placement on West Ship Island

## Ship Island

A potential borrow area was identified south of Ship Island. It has fine grain sand-sized sediments and thus is limited in its use within this project. Figure 6.3 shows the location, shape, and orientation of the borrow area. Despite the relatively large

sand deposit identified by the USGS' geophysics and the USACE vibracores, hydrodynamic modeling has played a role in reducing the extent and depth of the borrow area to mitigate its effects on the wave climate approaching East and West Ship Island. It is approximately 600 feet wide (north-south direction) and 6,000 feet long (east-west direction) covering a total area of approximately 96 acres with an average cut thickness of approximately 8 feet. It has an estimated volume of 2.7 million cubic yards and average D50 grain size of 0.21 mm. Dry Munsell color is expected to range from light brownish gray to light gray with an average dry Munsell value of 7. The average percentage of fines is expected to be approximately 6%.

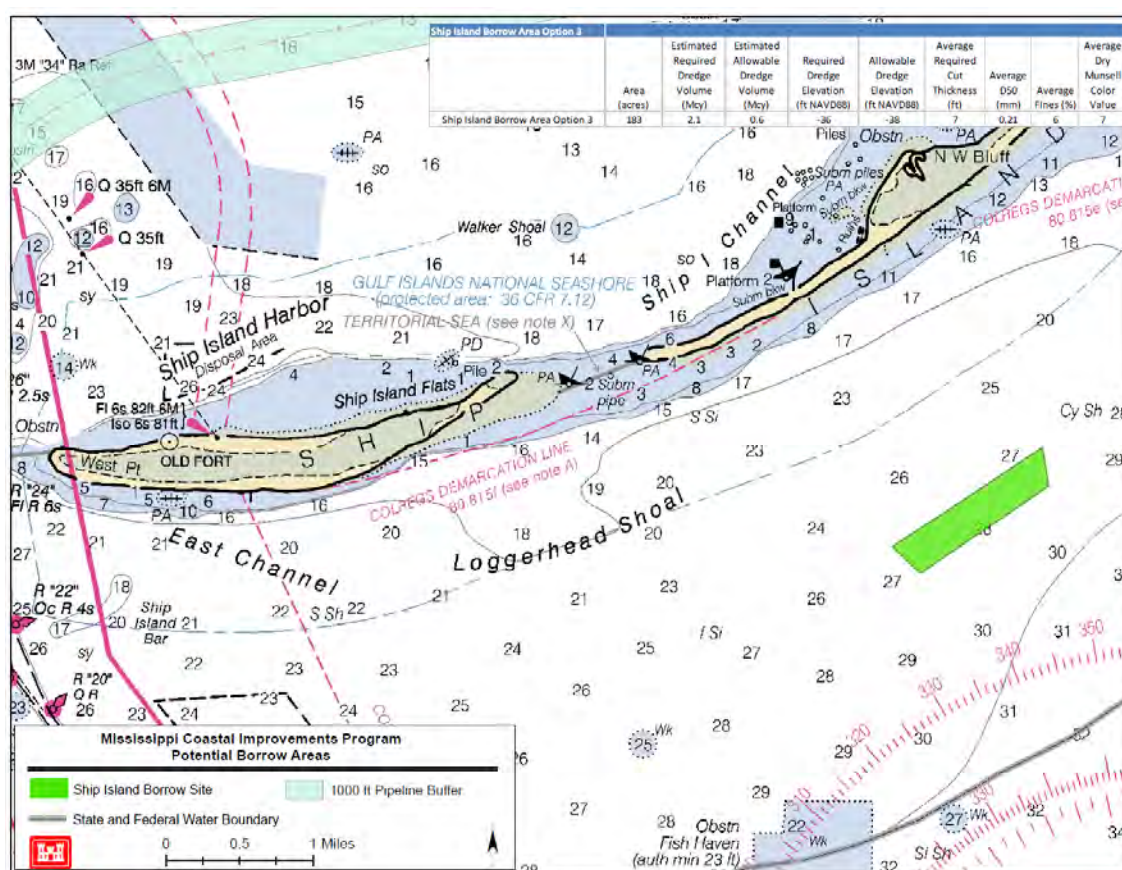

Figure 6.3 - Ship Island Borrow Area

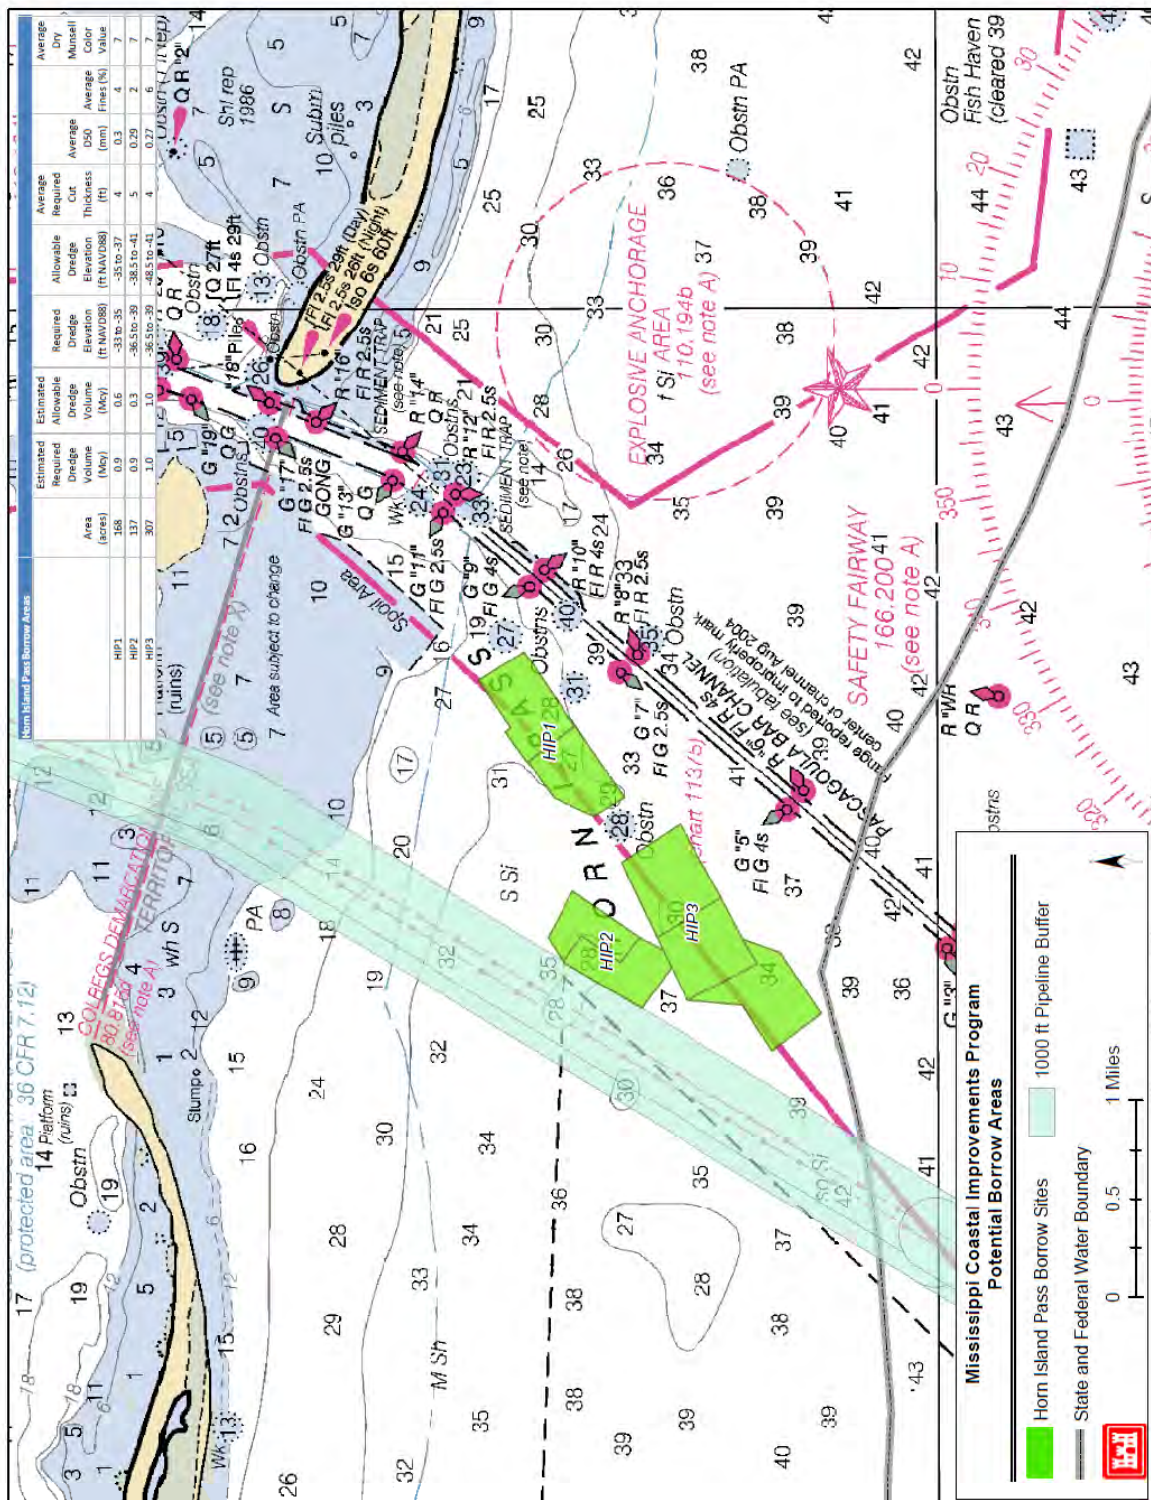

### Horn Island Pass

Three potential borrow areas have been identified within the Horn Island Pass sampling area that maximize use of the dredged sediment disposal mounds identified there (Figure 6.4). The borrow areas are located on top of the mounds,

which greatly influences their shape, size, and orientation. Because the mounded disposal sediments were mechanically placed on the seafloor, there is a fairly distinct transition between the sandy disposal sediments and the muddy in-situ sediments. The intent of the borrow area designs is to dredge down to this transition zone without dredging into the poor material. Each borrow area is split into different cells with cut elevations adjusted to the undulating bathymetry created by the mounds. Because of the difficulty in designing a borrow area on a convex surface, there is an area in HIP 3 that is considered allowable dredge material, but not required for the project. The purpose of this allowable area is to recognize that the material is suitable for the project, but that the difficulty in dredging it could increase project costs for the contractor. By making it optional, the contractor can decide if the cost is worth the effort to ensure the required quantities for the fill specifications are met.

The northernmost borrow area, HIP1, is divided into two cells with cut elevations of -33 (northern half) and -35 (southern half). The dimensions of the entire borrow area are roughly 4,700 feet long (northeast-southwest) by 1,600 feet wide (southeast-northwest). The combined area is approximately 168 acres, with an average cut depth of 4 feet. The total volume is estimated at 1.4 mcy of sand with an average D50 of 0.30 mm, fines content of 4%, and a Munsell Value of 7. The next borrow area, HIP 2, is located to the west of the southern tip of HIP 1. It contains two cells with cut elevations of -36.5 (northern half) and -39 (southern half), respectively. The dimensions of the entire borrow area are roughly 3,200 feet long (northeast-southwest) by 1,600 feet wide (southeast-northwest). The combined area is approximately 137 acres, with an average cut depth of 5 feet. The total volume is estimated at 1.3 mcy of sand with an average D50 of 0.29mm, fines content of 2%, and a dry Munsell Value of 7. The third borrow area, HIP 3, is located to the southwest of HIP 1 and south of HIP 2. It contains three cells with cut elevations of -36.5 (northern half) and -39 (southern half). The southwestern cell with cut elevation of -36.5 ft is allowable for the contractor, but not necessary. The dimensions of the entire borrow area are roughly 6,400 feet long (northeast-southwest) by 2,000 feet wide (southeast-northwest). The combined area is approximately 307 acres, with an average required cut thickness of 4 feet. The total volume is estimated at 1.2 mcy of sand with an average D50 of 0.27 mm, fines content of 6%, and a dry Munsell Value of 7.

### Figure 6.4 – Horn Island Pass Borrow Area

**Petit Bois Pass-Outer Continental Shelf West**

Six potential borrow areas were identified within the Petit Bois Pass-Outer Continental Shelf West sampling area (Figure 6.5). Because most of the suitable sand deposits are located within the confines of the shoals in the area, the borrow areas' shape, size, and orientation are highly dependent on the morphology of these shoals. There are also "Allowable" dredging cells within certain borrow areas that are the result of the deposit being too thinly bedded for a required cut, but thick enough for a contractor to dredge it, albeit most likely at a higher unit cost.

PBP-OCS West 1 is located approximately 4 miles south of Petit Bois Island on Shoal 2, described in Section 5.2.11.1. Because of the morphology of the shoal, the borrow area has one cell that is required dredging and a smaller southeastern cell that is "Allowable" dredging. The dimensions of the entire borrow area are roughly 8,800 feet long (northwest-southeast) by 2,100 feet wide (southwest-northeast). The combined area is approximately 419 acres, with an average required cut thickness of 5 feet. The total volume is estimated at 3.1 mcy of sand with an average D50 of 0.26 mm, fines content of 3%, and a dry Munsell Value of 6.

PBP-OCS West 2 is located approximately 2.7 miles south of Petit Bois Island on the western end of Shoal 3, described in Section 5.2.11.1. Because of the morphology of the shoal, there are three cells within the borrow area, and the northwestern and southeastern cells are "Allowable" for dredging. The dimensions of the entire borrow area are roughly 7,500 feet long (northwest-southeast) by 1,600 feet wide (southwest-northeast). The combined area is approximately 192 acres, with an average required cut thickness of 4 feet. The total volume is estimated at 1.6 mcy of sand with an average D50 of 0.28 mm, fines content of 5%, and a dry Munsell Value of 6.

PBP-OCS West 3 is located approximately 1.9 miles south of Petit Bois Island to the north of Shoal 3. This borrow area is relatively flat compared with the others in PBP-OCS West, but has a much thicker subbottom deposit of sand. Based on the deposit thicknesses, three cells were identified within the borrow area. The dimensions of the entire borrow area are roughly 7,000 feet long (northwest-southeast) by 2,100 feet wide (southwest-northeast). The combined area is approximately 275 acres, with an average required cut thickness of 9 feet. The total

volume is estimated at 5.5 mcy of sand with an average D50 of 0.26 mm, fines content of 3%, and a dry Munsell Value of 6.

PBP-OCS West 4 is located approximately 3.8 miles south of Petit Bois Island on the central portion of Shoal 3, described in Section 5.2.11.1. Because of the morphology of the shoal and the sediment deposit adjacent to it, there are two cells within the borrow area that target these features. The dimensions of the entire borrow area are roughly 5,500 feet long (northwest-southeast) by 1,650 feet wide (southwest-northeast). The combined area is approximately 195 acres, with an average required cut thickness of 8 feet. The total volume is estimated at 2.4 mcy of sand with an average D50 of 0.30 mm, fines content of 4%, and a dry Munsell Value of 6.

PBP-OCS West 5 is located approximately 5.2 miles south of Petit Bois Island on the eastern portion of Shoal 3 in the PBP-OCS West sampling area, described in Section 5.2.11.1. Because of the morphology of the shoal, there is one “Required” and one “Allowable” cell within the borrow area. The Allowable cell is located on the southeastern end of the borrow area. The dimensions of the entire borrow area are roughly 5,500 feet long (northwest-southeast) by 1,800 feet wide (southwest-northeast). The combined area is approximately 190 acres, with an average required cut thickness of 4 feet. The total volume is estimated at 1.3 mcy of sand with an average D50 of 0.28 mm, fines content of 4%, and a dry Munsell Value of 6.

PBP-OCS West 6 is located approximately 6.4 miles south of the eastern tip of Petit Bois Island on the eastern portion of Shoal 3 in the PBP-OCS East sampling area, described in Section 5.2.11.1. Because this portion of the shoal is relatively consistent in its thickness, there is only one dredge cell within this borrow area. The dimensions of the borrow area are roughly 3,600 feet long (northwest-southeast) by 1,590 feet wide (southwest-northeast). The area is approximately 146 acres, with an average cut thickness of 5 feet. The total volume is estimated at 1.5 mcy of sand with an average D50 of 0.29 mm, fines content of 2%, and a dry Munsell Value of 6.

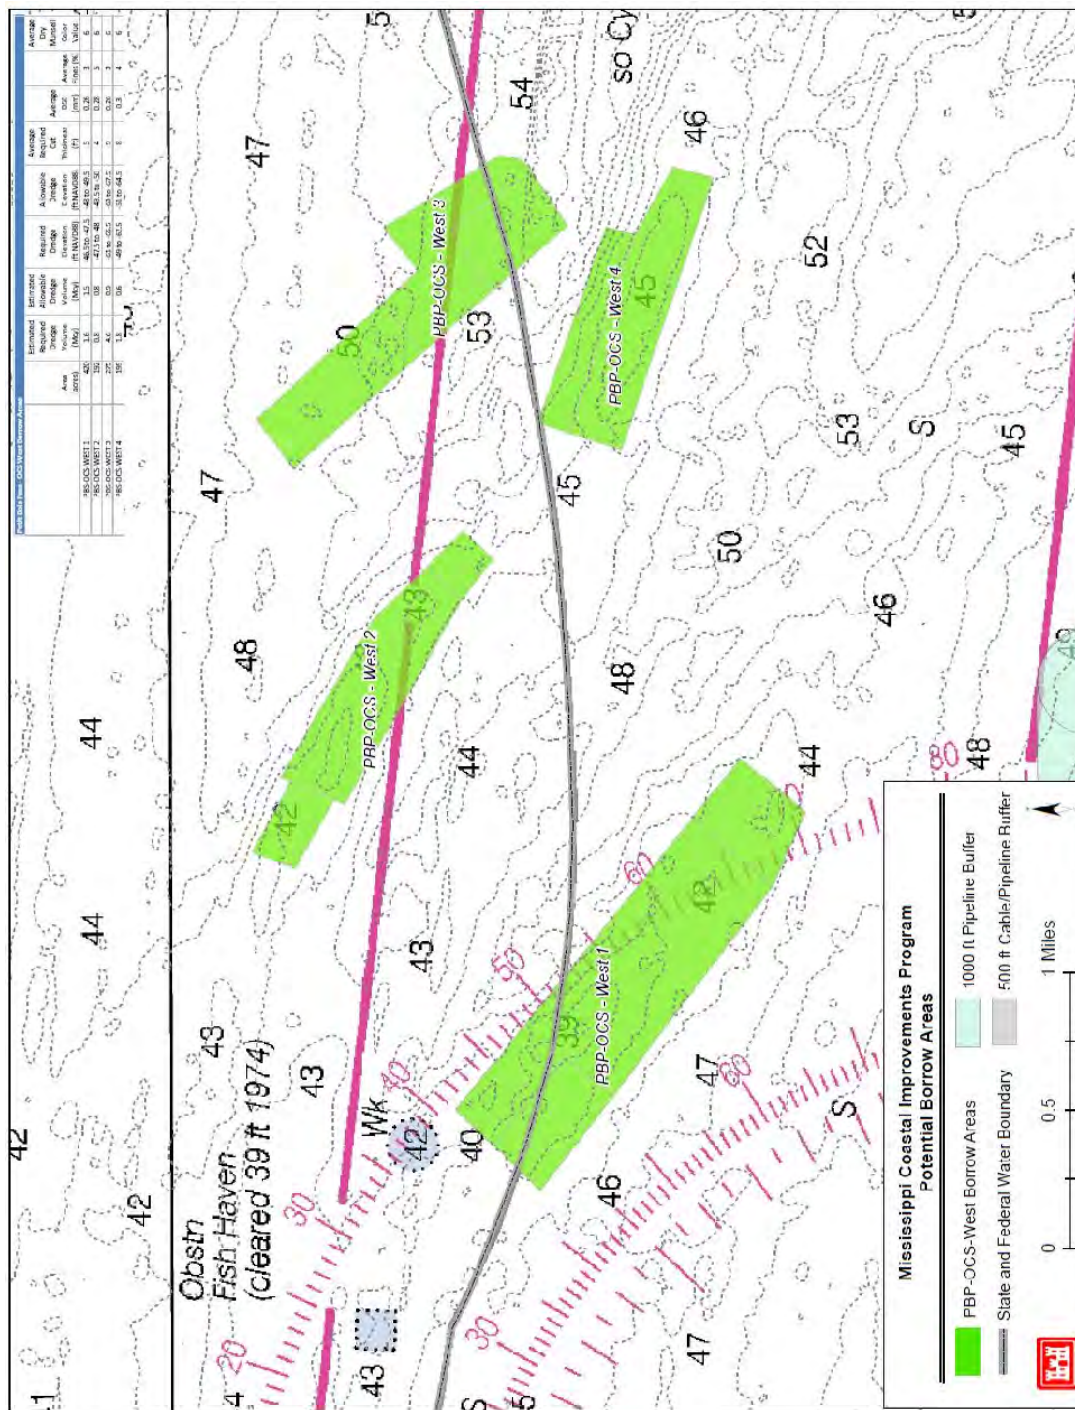

Figure 6.5 – Petit Bois Pass-OCS West Borrow Areas 1 thru 4

**Petit Bois Pass-Outer Continental Shelf East**

Five potential borrow areas were identified within the PBP-OCS East sampling area (Figure 6.6). Because most of the suitable sand deposits are located within the confines of the shoals in the area, the borrow areas' shape, size, and orientation are highly dependent on the morphology of these shoals. There are also "Allowable" dredging cells within certain borrow areas that are the result of the deposit being too thinly bedded for a required cut, but thick enough for a contractor to dredge it, albeit most likely at a higher unit cost.

PBP-OCS East 1 is located approximately 4 miles southeast of Petit Bois Island and 5.1 miles south-southwest of Dauphin Island, AL, in an area described in Section 5.2.11.2.1. Because of the morphology of the shoal, the borrow area has two dredge cells to maximize sediment recovery. The dimensions of the entire borrow area are roughly 2,850 feet long (northwest-southeast) by 710 feet wide (southwest-northeast). The combined area is approximately 51 acres, with an average required cut thickness of 5 feet. The total volume is estimated at 0.4 mcy of sand with an average D50 of 0.33 mm, fines content of 2%, and a dry Munsell Value of 7.

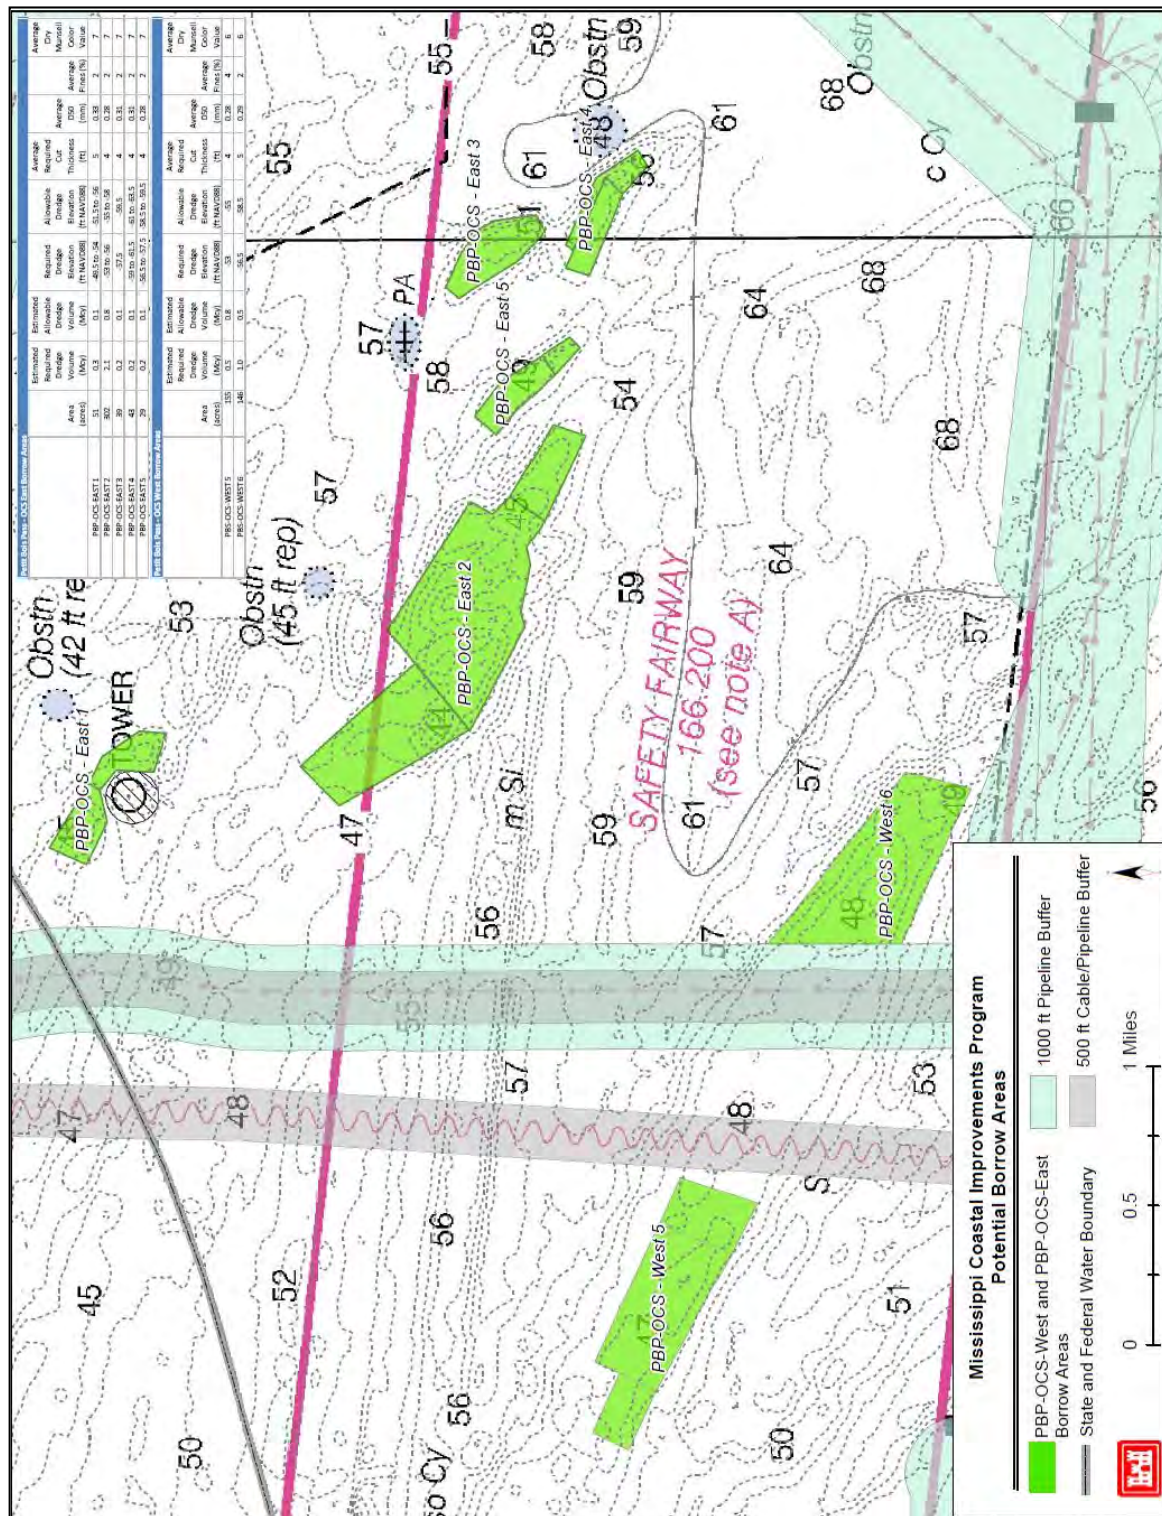

PBP-OCS East 2 is located approximately 5.5 miles south-southeast of Petit Bois Island and 6.3 miles south-southwest of Dauphin Island, AL, in an area described in Section 5.2.11.1. Because of the morphology of the shoal, there are three cells of different cut elevations within the borrow area to maximize sediment recovery. The dimensions of the entire borrow area are roughly 8,300 feet long (northwest-southeast) by 2,230 feet wide (southwest-northeast). The combined area is approximately 302 acres, with an average required cut thickness of 4 feet. The total volume is estimated at 2.9 mcy of sand with an average D50 of 0.28 mm, fines content of 2%, and a dry Munsell Value of 7.

PBP-OCS East 3 is located approximately 6.4 miles southwest of Petit Bois Island and 6.3 miles south-southwest of Dauphin Island, AL, in an area described in Section 5.2.11.2.3. This borrow area is located on top of a shoal and contains only one cut elevation. The dimensions of the entire borrow area are roughly 2,150 feet long (northwest-southeast) by 900 feet wide (southwest-northeast). The combined area is approximately 39 acres, with an average required cut thickness of 4 feet. The total volume is estimated at 0.3 mcy of sand with an average D50 of 0.31 mm, fines content of 2%, and a dry Munsell Value of 7.

PBP-OCS East 4 is located on a shoal approximately 6.8 miles southwest of Petit Bois Island and 6.8 miles south-southwest of Dauphin Island, AL, in an area described in Section 5.2.11.2.2. Because of the morphology of the shoal, there are two cells with different cut elevations within the borrow area that target the different thicknesses of the deposit. The dimensions of the entire borrow area are roughly 2,590 feet long (northwest-southeast) by 600 feet wide (southwest-northeast). The combined area is approximately 43 acres, with an average required cut thickness of 4 feet. The total volume is estimated at 0.3 mcy of sand with an average D50 of 0.31 mm, fines content of 2%, and a Munsell Value of 7.

PBP-OCS East 5 is located on a shoal approximately 6.2 miles southwest of Petit Bois Island and 6.5 miles south-southwest of Dauphin Island, AL, in an area described in Section 5.2.11.2.2. Because of the morphology of the shoal, there are two dredge cut elevations within the borrow area to maximize sediment recovery. The dimensions of the entire borrow area are roughly 2,330 feet long (northwest-southeast) by 590 feet wide (southwest-northeast). The combined area is approximately 29 acres, with an average required cut thickness of 4 feet. The total volume is estimated at 0.3 mcy of sand with an average D50 of 0.28 mm, fines content of 2%, and a dry Munsell Value of 7.

**Figure 6.6 – Petit Bois Pass-OCS West Borrow Areas 5 and 6, and PBP-OCS East Borrow Areas 1 thru 4.**

**Petit Bois Pass-MS**

The Petit Bois Pass-Mississippi borrow area is located approximately 1.4 miles southeast of the eastern end of Petit Bois Island (Figure 6.6). The borrow area covers the shoal described in Section 5.2.10. Because of the morphology of the shoal, there are five dredge cut elevations within the borrow area to maximize sediment recovery. The dimensions of the entire borrow area are roughly 3,500 feet long (northwest-southeast) by 2,370 feet wide (southwest-northeast). The combined area is approximately 175 acres, with an average required cut thickness of 6 feet. The total volume is estimated at 2.0 mcy of sand with an average D50 of 0.31 mm, fines content of 3%, and a dry Munsell Value of 7.

**Petit Bois Pass-AL West and East**

The Petit Bois Pass-AL borrow areas have been modified from their initial shapes to better fit the sand deposits and minimize wave refraction on Dauphin Island and surrounding pipelines (Figure 6.6).

PBP-AL East is located approximately 1.9 miles south of Dauphin Island, AL, in an area described in Section 5.2.9. There are five cells with different cut elevations targeting the different thicknesses of the deposit. The dimensions of the entire borrow area are roughly 1.9 miles long (west-east) by 5,750 feet wide (south-north). The combined area is approximately 885 acres, with an average required cut thickness of 7 feet. The total volume is estimated at 14.7 mcy of sand with an average D50 of 0.33 mm, fines content of 7%, and a dry Munsell Value of 6.

PBP-AL West is located on a shoal approximately 3 miles east-southeast of Petit Bois Island and 2.7 miles south-southwest of Dauphin Island, AL, in an area described in Section 5.2.9. There are three dredge cut elevations within the borrow area to maximize sediment recovery. The dimensions of the entire borrow area are roughly 6,800 feet long (west-east) by 2,450 feet wide (south-north). The combined area is approximately 380 acres, with an average required cut thickness of 6 feet. The total volume is estimated at 5.1 mcy of sand with an average D50 of 0.31 mm, fines content of 4%, and a dry Munsell Value of 6.

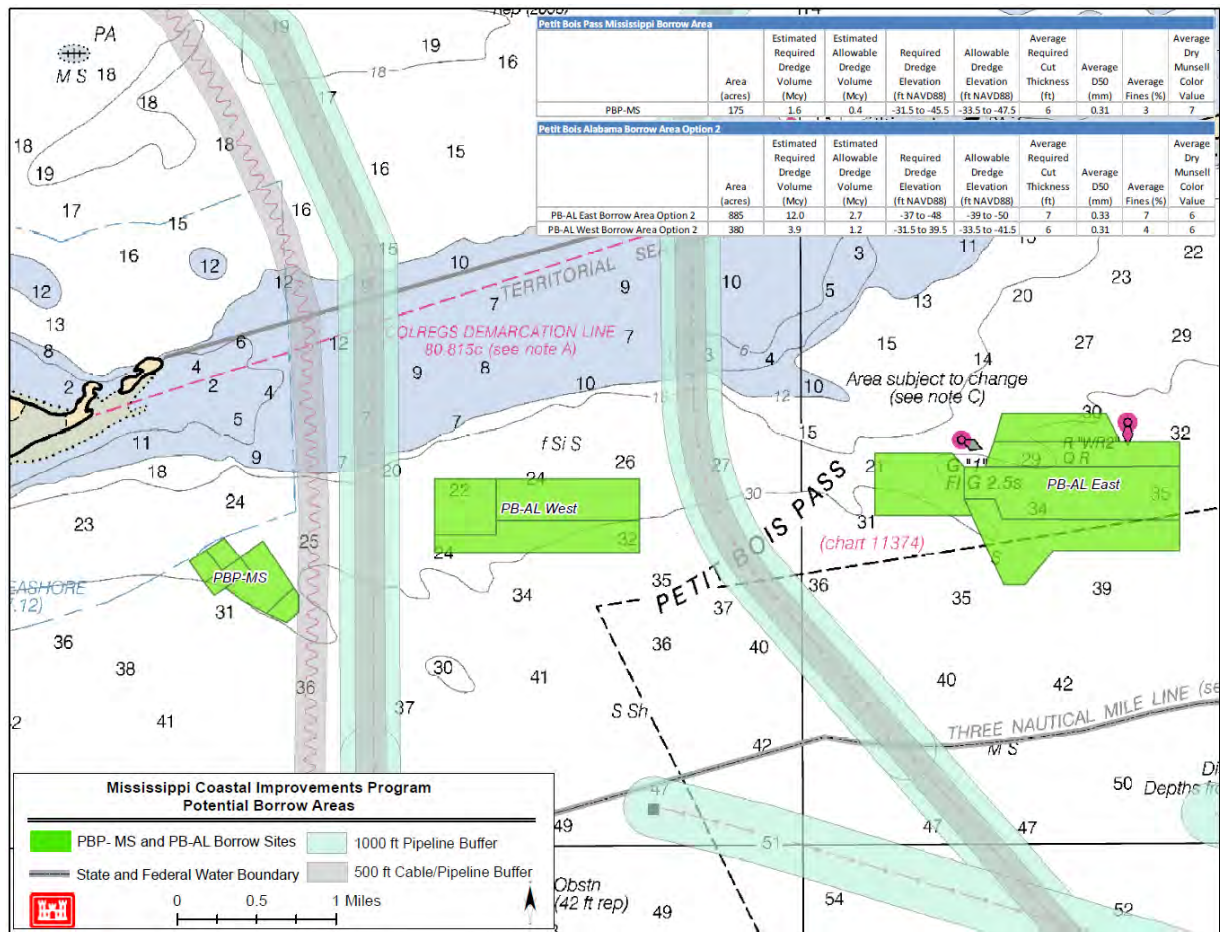

Figure 6.7 - Petit Bois Pass-AL Borrow Areas

## **7.0 CONCLUSION**

From 2006 through 2013, Mobile District conducted geotechnical investigations of the area surrounding the Mississippi Barrier Islands and south into Federally-controlled waters with the intent of identifying sediment characteristics of the islands and locating compatible sediment for nourishment projects on and around the islands.

Beginning in 2006, grab samples were taken on each island of the barrier island chain to identify each island's sediment characteristics in order to gain an understanding of the system as a whole. This information was critical to determining the type of sediment needed for island restoration projects in the area.

This was followed up with geophysical investigations conducted in conjunction with the USGS in 2010 and 2013 to identify offshore sand bodies that had the potential to be used as borrow sources.

Geotechnical investigations in 2010, 2011, 2012, and 2013 focused on potential sand deposits identified by the geophysical surveys and previous sampling events. Vibracoring was used to sample the sediments along the Mississippi barrier islands, specifically in Gulfport Channel, Mississippi Sound, adjacent to Cat Island, Ship Island Pass, south of Ship Island, Dog Keys Pass, Horn Island Pass, south of Petit Bois Island, and Petit Bois Pass. These vibracores assisted in refining the geophysical models to better locate sand sources and helped delineate potential borrow areas.

Potential borrow areas were identified and delineated in the investigation areas of Cat Island, Ship Island, DA-10, Petit Bois Pass-MS, Petit Bois Pass-OCS, and Petit Bois Pass-AL. A seventh borrow area, adjacent to West Ship Island, has already been utilized. These areas have undergone refinement through modeling and dredging industry input, but are still subject to change as new data becomes available (e.g. preconstruction surveys). Overall, approximately 24.9 mcy of suitable sand were identified for use in the barrier island projects.

-43.3	6.0		SAND, clayey, mostly fine-grained sand-sized quartz, some clay, trace shell fragments, gray (SC)	NS			
-46.3	9.0		SAND, silty, mostly fine-grained sand-sized quartz, some silt, trace shell fragments, clayey lenses, gray (SM)	B	Classification: SM Color: 5Y 5/2-olive gray D50: 0.1921 mm % Fines: 12.6		
-51.3	14.0		SAND, clayey, mostly fine-grained sand-sized quartz, some clay, trace shell fragments, gray (SC)	NS			
-52.6	15.3		CLAY, fat, mostly clay, trace fine-grained sand-sized quartz, soft, gray and brown (CH)				
NOTES: 1. Soils are field visually classified in accordance with the Unified Soils Classification System. 2. NS = Sample not submitted for laboratory analysis from this interval. 3. Seafloor elevation calculated using sampling vessel's fathometer water depth reading and applying NOAA tidal gauge data conversion factor.
